 ZAKRZEWSKA, M. E., M.D.

INDEX TO VOLUME CXVIII.

- Abbott, S. W.** Recent progress in public hygiene, 369.
 "About the size of a—," 187.
Abscess. A case of pelvic abscess: death from hemorrhage, Hubbard, E. T., 570.
Adams, H. F. Antiseptic midwifery, 217, 223.
Adenoid Growths. Adenoid vegetations in children: their diagnosis and treatment, Hooper, F. W., 261, 273; relation of adenoid growths in the naso-pharynx to the production of middle ear disease in children, Blake, C. J., 268, 272; operating for adenoid growths, Johnson, T. D., 438.
Advertisements. Medical advertisements and the religious press, 577.
Agaricine, 462.
Albuminuria. Shepherd, G. R., 575; albuminuria in the apparently healthy, Stokes, F. H., 385.
Alcohol. The use of alcohol in certain forms of fever, Kretschman, 179; alcohol as a therapeutic remedy, Binz, C., 466.
Alcoholic Paralysis, 607.
Alexander's Operation. Six cases of Alexander's operation, Strong, C. F., 166, 251.
America. Comparative mortality in England and in America, 53.
Ankylen-Hydrat, Williams, F. H., 176.
Anatomy. Recent progress in anatomy, Dwight, T., 451.
Aneurism of the arch of the aorta, Greene, J. S., 273.
Ankle. Result of resection of the ankle-joint, Cabot, A. T., 289.
Antifebrin. Antipyrene and antifebrin as nervous sedatives: comparison with solanin, 460; the superiority of antifebrin over the antipyretics, 553.
Antipyretics. Fever and the use of antipyretics, Gage, J. A., 113, 137.
Antipyrene. Antipyrene in the treatment of chorea, 303; unpleasant lung symptoms following the use of antipyrene, Storge, W., 409; antipyrene and antifebrin as nervous sedatives: comparison with solanin, 460; treatment of polyuria by antipyrene, 461; the monopoly of antipyrene, 508.
Antiseptic Surgical Cabinet, Getz, H. L., 573.
Aphemia, 31.
Apothegm mineral water, Cutler, E. G., 124.
Apostoli's treatment of uterine fibroids by electrolysis, Thornton, K., 110.
Appendicitis, with report of cases, Vickery, H. F., 29, 41; appendix vermiformis: its functions, pathological changes, and treatment, Smith, H. A., 530; the cæcum and appendix: their relations in health and disease, Ranschoff, J., 551.
Armaamentarium. The country physician's armaamentarium, 306.
Armstrong, H. More alleged milk infection through scarlet fever, 410.
Army. Report of the surgeon-general, 49.
Arm. An excision in the extemporization of liters from rifles and gunslings, Pritch, E. E., 565.
Arnicæ. The physiological action of arnica montana on the circulation, Hare, H. A., 41.
Arsenic. On motor paralysis and other symptoms of poisoning from medicinal doses of arsenic, Putnam, J. J., 165.
Arsenical Paper Hangings. The value of wall-paper guarantees, Harrington, C., 215.
Aspirator. A new aspirating apparatus, Knaut, 135.
Asphyctic Sports. Excesses and abuses in athletic sports, 459.
Australia. The utilization of disease for the destruction of rabbits in Australia, 461.
Auvard. *Viburnum prunifolium*, 305.
Bacilli. Destructive action of boiling water on typhoid bacilli, Vichur, 185; bacilli of tuberculosis in the urine, Gannett, W. W., 321.
Bacon, F. The relation of the insane to the law in the State of Connecticut, 573.
Ballley, E. H. S., and Nichols, E. L. The delicacy of the sense of taste, 329.
Barker, F. Acute Bright's disease in the puerperal state, 181.
Bartholow, R. Address on general medicine, 564.
Basewood's disease, with antiseptic, Roosevelt, J. W., 324.
Baths. The cold-bath treatment of fevers, 129.
Beach, H. H. A. Cancer of the tongue: complete extirpation by a bloodless operation, 364; hypoplasia, 375; multiple fatty tumors, 378; two cases of cancer, 548; a case of cancer of the prostate gland, 621, 627.
Beane, F. D. An anomalous case of hematoma, 148.
Bernarda. Letter from Bernarda, Brainerd, J. B., 411.
Bibliography. Books of health report, 1887, 483; Bradley, E. N., *L'iodisme*, 128; Brown, F. H., the Medical Register for New England, 163; Byford, W. H., and Byford, H. T., the practice of medicine and surgery applied to the diseases and accidents incident to women, 153; Chapman, H. C., treatise on human physiology for the use of students and practitioners of medicine, 380; cyclopaedia of obstetrics and gynecology, V, 432; Earle, P., the curability of insanity, 47; Fox, G. H., photographic illustrations of skin diseases: an atlas and text-book combined, 301; Hare, H. A., questions and answers on the essentials of physiology, prepared especially for students of medicine, 482; Harvard Medical School, annual report, 1886-87, 183; Hudson, E. D., a manual of the physical diagnosis of thoracic diseases, 422; Index medicus, 395; Jennings, C. G., practical urine testings: a guide to office and bedside urine analysis, 277; Johnson, G., medical lectures and essays, 277; Leaming, J. B., diseases of the chest, 432; Livingst, R., a handbook on diseases of the skin, with special reference to diagnosis and treatment, 302; Marsh, diseases of the joints, 326; Massachusetts General Hospital and McLean Asylum, annual report, 280; Mears, J. E., transactions of the American Surgical Association, 1877, 277; Miller, practical microscopy, 302; Miner, J. A., Miner's new index rerum for students and professional men for saving knowledge, 405; Mitchell, S. W., doctor and patient, 301; Money, A., treatment of disease in children, including the outlines of diagnosis and the chief pathological differences between children and adults, 229; Oertel, M. Y., handbook of general therapeutics, Ziensen, VII, therapeutics of excretory derangements, 432; Porter, J. A., the surgeon's pocket-book, 48; psychology, the American Journal of Psychology, 570; Randall, R. L., and Morse, H. L., photographic illustrations of the anatomy of the human ear, together with pathological conditions of the drum-membrane, 128; Rensen, J., the principles of theoretical chemistry, with special reference to the constitution of chemical compounds, 277; Smith, E., on the wasting diseases of infants and children, 353; Smith, J. V., abdominal surgery, 581; Smith, S., the principles and practice of operative surgery, 481; Surgeon-General, U. S. A., annual report, 48; Vermont Asylum for the Insane: its annals for fifty years, 302; Walker, J., health lesson: a primary book, 49; Williams, C. J., and Williams, C. T., pulmonary consumption: its etiology, pathology, and treatment, 580; Woakes, E., nasal polypus, with neuralgia, hay fever, and asthma in relation to ethmoiditis, 229; Yeo, G. F., a manual of physiology: a text-book for students of medicine, 466.
Bedwell, W. D. Many living generations, 535.
Bell. The doctor's bill, 258.
Billings, J. S. The history of medicine, 29, 57; ovariectomy in age, 628.
Binz, C. Alcohol as a therapeutic remedy, 466.
Biography. Agnew, C. R., 437; Butler, A. M., 557, 560; Carpenter, W. M., 55; Clark, A., 62; Clarke, R. L., 160, 510; Crosby, J. A., 134; Cross, E., 536; Davis, E. H., 534; Dawson, R. F., 284; Dean, J., 134; Drake, T. E. S., 281; Dunster, E. S., 536, 541; Fulton, A., 284; Gray, A., 134; Goldard, W., 558; Goldsmith, M., 52; Goldsmith, W. E., 332, 388, 510; Holder, J. B., 256; Jones, G. S., 369; Linsly, J., 524; Loring, E. G., 449, 462, 566; Mullen, F. H., 188; Musser, M. E., 282; Nichols, J. R., 25, 28; Palmer, A. E., 96; Parker, R., 45; Pritchney, H., 534; Priest, G. A., 488; Smith, N., 560; Spalding, J., 160; Swallow, E. E., 28; Varick, T. R., 62; Warren, C., 169; Weiss, J. A., 81; Wellington, C. B., 232, 284.
Blair. A new method in the surgery of the bladder, Newell, O. K., 465; intra-peritoneal rupture of the bladder, Grant, H. H., 579; dry medication in the treatment of urethra and bladder, Lee, E., 579.
Blair, C. J. Two cases illustrating the effects of pressure from polyp in the middle ear, 161; relation of adenoid growths in the naso-pharynx to the production of middle ear disease in children, 268, 272.
Blair, G. Protracted gestation, 164, 177; hydatiform mole, 502.
Blodgett, A. N. Twelve years in the development of a case of moral imbecility, 537, 549.
Bloomington Asylum. Removal of Bloomington Asylum, 484; Bloomingdale Asylum to be removed, 522.
Boldin. The hypnotic action of boldin, Jaramville, 158.
Bone. Selected cases of sarcoma in bone, with presentation of specimens and microscopical sections, 47; a case of hydatids in bone, Lessack, 514; the re-impaction of a trephine burr in bone, Burrell, H. L., 222, 313; myositis ossificans, London, 350.
Boric acid and linin in certain diseases of the skin in children, Sturgis, R., 193, 198.
Boston. Report of the Board of Health, 1887, 483.
Bowditch, F. H. On the action of caustic applications on the nasal mucous membrane, 180.
Bovine disease and scarlet fever, 167.
Bowditch, H. F. The reinforcement and inhibition of the knee-joint, 149.
Bradford, E. H. The treatment of inflammations in the neighborhood of the cæcum, 53; cases of open incision in wry-neck, contracted knee, and talipes varus, 285, 292; the treatment of lateral curvature, 445, 455; a large sequestrum from the temporal bone,

- 455; a new method of forcible correction of old subluxations of the tibia, 553.
- Bradford, E. H., and Lovett, R. W.** Report of progress in orthopedic surgery, 519, 566.
- Brain Injury.** 158.
- Brauner, J. B.** Letter from Bermuda, 111.
- Brasão, J.** Sanatorium in Brazil, 110.
- Brown, A.** The human breath a poison, Brown-Sequard, 209.
- Bridge, S. Jr.** Norman Bridge, in the Cook County Hospital, 110.
- Bright's Disease.** Mental affections associated with chronic Bright's disease, Osler, W., 53; acute Bright's disease, Deland, F., 180; acute Bright's disease of children, Jacobi, A., 180; changes in the eye in Bright's disease, B. St. J., 181; on the cardiac changes in acute Bright's, Van Santvoord, K., 181; acute in the puerperal state, Barker, F., 181; the treatment of acute Bright's, Ely, W. S., 181.
- Brown, E. B.** Preventive treatment in the primary stage of syphilis, 254.
- Brouardel, Hermaphroditism, 51.**
- Brown-Sequard.** The human breath a poison, 209.
- Brunton, T. L.** Stricture as a hypomye, 156.
- Crush, E. F.** Bovine tuberculosis, 179.
- Bryant, J. W.** Treatment of penetrating gun-shot wounds of the cranium, 203.
- Buckingham, E. M.** Nocturnal incontinence of urine, 270, 273.
- Burchard, T. H.** The modern treatment in strangulated hernia, 15.
- Bullard, W. N.** Cases of febrile delirium tremens, 144, 149; a case of cerebral localization with double trephining (acquired spastic hemiplegia)—arterio-phasia, 162, 170.
- Bullard, W. N., and Brackett, E. G.** Static equilibrium, 132.
- Gurrell, H. L.** The re-implantation of a trephine button of bone, 313, 322.
- Burrell, H. L., and Cushing, H. W.** Report on progress in surgery, 315, 350, 372.
- Cabot, A. T.** Result of resection of the ankle-joint, 289; notes on complications met with in cases of strangulated hernia, 308, 321; cases of vesical and urinary calculus, 375.
- Caille, A.** A method of prophylaxis in diphtheria, 125; case of general muscular contracture, 263.
- Calculus.** Case of vesical and urinary calculus, Cabot, A. T., 375; multiple salivary calculus, Moscov, N., 4, 284.
- California.** Southern California as a health-resort, Dutton, S. L., 479.
- Cancer.** Chian turpentine treatment of cancer, Lewis, D., 236; two cases of cancer, Beach, H. H. A., 548; the physical examination of the stomach, and the value of the absence of free hydrochloric acid as a sign of cancer, 554; a case of cancer of the prostate gland, Beach, H. H. A., 621, 627; a case of cancer of the rectum, Warren, J. G., 626.
- Cañon City.** Certain advantages of Cañon City, Colorado, as a resort for consumptives, Lord, W. T., 257.
- Capital punishment by electricity, 107.**
- Carbuncle.** The treatment of carbuncle by carbolic spray, 257.
- Charles Wright Lectures.** The general pathology of fever, Welch, W. H., 125, 261, 313.
- Casini, A.** A case of splenectomy, 637.
- Caslie, F. A.** Medical treatment of salpingitis, 291.
- Catherin, O.** Simple extraction of cataract, Knapp, H. B., 349.
- Chloralbin.** Medicine for hysterics, 375.
- Chandler, T. H.** Another view of dentists' patients, 259.
- Channing, W.** Progress in the care of the insane, 324; five living generations, 539.
- Cerebro-spinal Meningitis.** Gaston, J. McF., 577.
- Cheever, D. W.** The substance of doubtful tumors under the use of alternative medicine, 620, 628.
- Chemistry.** Report on medical chemistry, Hills, W. B., 392.
- Chicken turpentine treatment of cancer, Lewis, D., 235.**
- Chicken Skin.** The treatment of denuded surfaces by chicken skin grafts, 556.
- Children.** Remarks on strangulated hernia in children, Gerster, H. G., 17; treatment of the intestinal invagination in children, Herz, 26; an epidemic of pneumonia among children, Tresselt, F., 55; 19; catenches of urine in children, Townsend, C. W., 158; acute Bright's disease in children, Jacobi, A., 180; on the use of lanolin and boracic acid in certain diseases of the skin in children, Sturgis, K., 193, 195; case of general muscular contracture, Smith, M., 295; case of infantile paralysis, Smith, J. L., 294; sepsis in the newly-born, Jacobi, A., 295; a contribution to the study of cerebral paralysis in infancy, Seibert, A., 295; recurrent erysipelas in a child, Koch, T. M., 242; infantile cerebral tuberculosis, Roth, T. M., 250; adenoid vegetations in children: their diagnosis and treatment, 261, 272; relation of adenoid growths in the nasopharynx to the production of middle ear disease in children, Blake, C. J., 265.
- Cholera.** Cholera infantum and the weather, Seibert, A., 293; a study of break of typhoid fever in a child's home, Hilyoke, W. G., 173; the sterilization of milk for infants, Jellies, J. A., 397; infant-feeding, Woodbury, E., 594; typhoid fever in a child three years of age, Farahan, E., 599.
- Cholera infantum and the weather, Seibert, A., 293.**
- Chorea.** Antipruric in the treatment of chorea, 363.
- Circular Insanity.** 59.
- Circulatory System.** The physiological action of aranea montana on the circulation, Harb, B. A., 41; note on an anomalous arrangement of the large veins of the neck, Pinkham, J. G., 118; on the cardiac changes in acute Bright's, Van Santvoord, K., 181; pericarditic hemorrhage, Putnam, J. J., 290; a fatal case of pulmonary blood-embolism occurring during labor with twins, Green, C. M., 243, 252; report on progress in thoracic disease, Shattuck, F. C., 241; aneurism of the arch of the aorta, Greene, J. S., 573; hydropy of the heart, Green, J. S., 574; a fatal case of rupture of arterial tension in neurasthenia, Webber, S. G., 411; embryocædema; the lowered arterial tension in typhoid fever; therapeutic indications, 531.
- Clarke, M. D.** Therapeutic nihilism, 624.
- Climatic.** A layman's view of winter health-resorts, 79; on the selection of a climate for patients with pulmonary tuberculosis, 15.
- Knights, F. L., 343, 353; on the treatment of phthisis pulmonalis by sojourn in elevated climatic stations, 582.**
- Colds.** The treatment of colds and bronchitis, 569.
- Cancer, P. S.** Sarcoma of the acromioclavicular joint, 579.
- Constipation and some of its accompaniments, Hodges, R. M., 370; postural treatment of constipation, Williams, E. T., 449.**
- Corning, J. L.** Neuro-therapeutic memoranda, 179; direct medication of the spine, 509.
- Corrosive Sublimate in treatment of typhoid fever, 267; the value of corrosive sublimate as a practical disinfectant, Hills, W. B., 651.**
- Cotting, B. E.** Professional reminiscences, 1, 32, 61, 80.
- Cranium.** Treatment of penetrating gunshot wounds of the cranium by the use of the trephine, 203; demonstration of the cranial and telephonic probe, Gardner, J. H., 203; extensive cranial fracture; considerable loss of brain substance, complicated with fungus cerebri, Matheson, A. R., 203; fracture of the skull, with depression, Flood, H., 205.
- Currier, A. F.** The influence of obesity in young women upon the menstrual and reproductive functions, 179.
- Curtis, B. F.** Results obtained by operative interference (in cases of intestinal obstruction), 275.
- Cushing, E. W.** Committee on ethics and discipline of the Massachusetts Medical Society and the Moulton Liquid Food Hospital, 282.
- Cushing, H. W.** Foot crushed by a locomotive, 626.
- Cutaneous System.** The connection between erythema nodosum and rheumatism, Mackenzie, S., 82; notes on the treatment of lupus, Pittard, H. G., 180; xeroderma pigmentosa and its relation to malignant new growths of the skin, F. H., 227; dermatosis following initial shock, Dubois-Haveth, 456.
- Cutler, E. G.** Apohagi mineral water, 121.
- Dana, C. L.** Thompson's disease, 323.
- Davenport, F. H.** Report of progress in gynecology, 95; uterine displacements and their influence on the general nervous system, 621.
- Davis, T. P.** Gradual dilatation of esophageal strictures, 602.
- Dead Bodies.** The preservation of dead bodies, Suiter, W., 224.
- Deane, W. H.** Diabetes mellitus in an infant, Deane, W. H., 157; the value of so-called diabetic foods, Harrington, C., 286, 291; Johnson's Educators as a diabetic food, Johnson, W. L., 411; diabetic foods containing starch, Harrington, C., 438; diabetic food, Roth, A. C., 510; diabetic mellitus, Keegan, 462.
- Didama.** Five very obstinate cases of hamaturia, 578.
- Digestive System.** The modern treatment in strangulated hernia, Burchard, T. H., 15; how shall the sac be treated by external herniotomy? W. B., 17; the conservative treatment of irreducible and incarcerated hernia, De Garmo, W. B., 17; remarks on strangulated hernia in children, Gerster, H. G., 17; the treatment of hernia, 23; treatment of intestinal invagination in children, Herz, 26; appendicitis, perforation of the vermiform appendix, Richardson, M. H., 88, 99; the treatment of inflammations in the neighborhood of the cæcum, Bradford, E. H., 93, 99; a case of stricture of the rectum treated by incision, Reynolds, E., 57, 99; a case of perityphilitic abscess bursting into the intestine; recovery, Doe, G. W., 103, 105; surgical interference in perityphilitis, 105; peritonitis ante-partum, Goe, 158; results of mechanical treatment of 1,600 cases of hernia in private practice, De Garmo, W. B., 180; stone in the stomach, 156; a case of sarcoma of the tonsil removed by external herniotomy, W. B., 17; a case of stricture of the rectum for the presence of hydrochloric acid in the gastric juice; the recent discussion before the Academy of Medicine, 206; the pathology and symptoms of intestinal obstruction, Stimson, L. A., 234; how long should operative measures be resorted to? Vanderveer, A., 234; when should enterostomy be chosen? Park, R., 225; how should the operation be conducted? Weir, R. F., 225; results obtained by operative interference, Curtis, B. F., 225; annual report of the Academy of Medicine of Brighton's disease, 234; a case of intra-uterine conception in a child twenty months old, Swift, W. N., 246; notes on complications met with in cases of strangulated hernia, Cabot, A. T., 309, 321; strangulated inguinal hernia; herniotomy; contents of sac removed by herniotomy; relief of symptoms, Matheson, A. R., 315, 321; laparotomy for tubercular peritonitis, Romans, J., 329; constipation and some of its accompaniments, Hodges, R. M., 376; multiple salivary calculi, 386; tuberculosis of the peritoneum; evacuation of ascites by laparotomy; relief of symptoms, Matheson, A. R., 329; a contribution to the study of gastro-intestinal antisepsis, 507; the appendix vermiformis: its functions, pathological changes, and treatment, Smith, H. H., 530; the cæcum and appendix: their relations in health and disease, Kausloff, 571; a case of typhoid fever, with extensive gangrenous recovery, Murphy, L. S., 551; intestinal obstruction in its surgical aspects, Penrose, C. B., 552; use of hydrogen gas in the diagnosis of injuries of the abdomen, Seim, N., 552; some obscure affections of the sigmoid flexure, Matheson, A. R., 553; the treatment of cases of gastric disease, Knapp, F. C., 561, 571; diagnosis and treatment of diseases of the stomach, Pepper, W., 576; gradual dilatation of esophageal strictures, Davis, T. P., 602; case of cancer of the rectum, Warren, J. C., 626; postural treatment of constipation, Williams, E. T., 649.
- Diphtheria.** Present opinions regarding the pathology and treat-

- [illegible]

- Gout.** The dietetic treatment of gouty diathesis, Draper, F. W., 262.

Address.

PROFESSIONAL REMINISCENCES.¹

BY BENJAMIN EDDY COTTING, M.D., ETC.

Mr. President, and Fellow-Members of the Norfolk District of the Massachusetts Medical Society:

THE officers of our Society have directed me to prepare a paper for this meeting. Having long and earnestly maintained that every member should attempt for the Society any duty assigned to him, I cannot consistently refuse to undertake the task now imposed upon me.

Although the subject enjoined and the topics indicated are not such as I would have chosen — involving, as they must, an unpurposed unfolding of self-matters — it is quite possible that an unvarnished story of some of the "labors, dangers and sufferings" of an old soldier, while groping in the mistiness of past times, may not be without interest to abler warriors, thrice armed with all modern improvements and in the light of the present, but even now in a perpetual struggle along the same line of oft-perplexing service.

At all events, the mandate should be obeyed; it is official, and "to be respected accordingly."

Repressing, therefore, personal disinclinations, and premising that I have scarcely any notes to refer to, I will endeavor to relate, as best I may, a few of the wayside incidents of my professional career.

I have now practised medicine for a full half-century. Fifty years ago, last August, on commencement-day, three years after graduating at Harvard University, I received at the hands of its President a degree of Master of Arts; and, after that, but on the same day, a diploma conferring, as it said, "all the rights, honors, and privileges pertaining" to a Doctor of Medicine.

A few weeks later I was admitted a Fellow of the Massachusetts Medical Society, and obtained its "License to become a practitioner of Medicine and Surgery . . . while a resident within the Commonwealth" of Massachusetts.

Armed and equipped with these formidable documents, a very bashful but an undaunted youth, I proceeded at once to affix to the door of my lodgings an indication that thereabouts did dwell a new recruit in the "great army" of those who, in the words of its foremost leader, are ever ready.²

¹ "To do a world of good, and take a world of pay."

The professional "shingle" having been thus duly adjusted, a hasty retreat was effected, and the door bolted; lest some great accident or some pressing emergency should, perchance bring excited messengers too suddenly before the startled and inwardly-trembling neophyte. But no accident happened, no emergency arose. Perhaps it was the *sign*, it seemed indeed to say

"The smallest fevers gratefully received;"³

but it may have been too inconspicuous to be read by one who runs. It was indeed a modest affair compared with many since exhibited, — an early effort, by the way, of one who long ago became a noted

landscape painter. It is still in service, in humble contrast with what fashion or greater acquirements have since seemed to demand.

I have been urged to tell, especially, of my first lodgings, the fittings-up thereof, my manner of living there, the books and instruments then thought necessary — for display, if not for study and use — that these things may be compared or, rather, contrasted with the requirements of young beginners of the present day. It is a sorry story; but here are some of the *res angustæ domi*.

In selecting lodgings the chief points were to get as near as possible to where other and older practitioners were congregated; and to be accessible to Dispensary and other equally promising districts, from which employment might at first be expected. I tried for Winter Street, then full of doctors, but the best accommodations obtainable, within my limited means, were on Washington near Bedford Street.

As it was, I was obliged to go up one flight, and to take a single room. It was forlorn enough, with bare, unpapered walls; and a hole in one side of it for a stove, if I could obtain one. I arranged a cot in one corner, and concealed it, as best I could, with a muslin curtain of no very elegant pattern or artistic construction. A fragment of a carpet on the middle of the floor; a pine table, with four attenuated legs supporting its corners and a cover of green baize, for a centre-piece; and three or four wooden chairs — one a rocking-chair which subsequently had a history — completed the furnishings. On the table were a dozen or more books, chiefly medical; and a well-worn dissecting case of the ordinary pattern.

What would a young beginner nowadays think of such a "den" as this?

Not many days after I took possession of my apartment, while quietly settling down to the dreary drowsiness of solitude and want of occupation, I was aroused from incoming torpor by one of the most gratifying surprises I ever experienced.

A Professor of the Medical School,⁴ — waiving the usual etiquette and custom which required the new-comer to make the first calls — came to my office. We had never been introduced; and an absurd custom clinging to some of us from under-graduate usages had prevented my speaking to him, except in answers to examination questions, while he was a teacher and I a student, lest it should induce the accusation of "fishing," or the seeking of favors and indulgences. He brought to me some publications of recent cases, and asked me to assist him in a private operation. Thus began an intimate and mutually-confiding friendship which terminated only with his life.

Weeks passed, and yet the public did not appear to care for the patient waiter behind the door, nor seem very much to need his services.

Hitherto all my needs had been amply supplied; but now, while money could still be had for the asking, I had fully determined not to ask for more. On the contrary, I entertained a faint hope that sometime I might be able to pay back what I had received subsequently to leaving college. But, that aside, the present was to be provided for. It would not do to expect that to-day's expenses might be paid by to-morrow's incomings. Such a course would soon lead to

¹ Read, in part, before the Norfolk District Medical Society, October 28, 1887.

² Dr. Jacob Bigelow — P. B. K. Poem, 1831

³ Dr. O. W. Holmes once said that every young Doctor's new sign declares this. Fevers, the first e in prey — Hibernice, favers.

⁴ George Hayward, M.D., etc., Professor of Clinical Surgery in Harvard University. The silver pitcher, now in possession of the Massachusetts Medical Society, he gave to me, some years later.

distress and discomfiture. But, as was then recognized and afterwards fully realized, it would often be a hard trial to subsist upon the little actually received, rather than to venture upon that which, though earned, had not been paid in. The prospect was unpromising, but the will was strong; and the many obstacles were at last overcome. The first steps were the worst.

Although a *voluntary* undertaking, nevertheless to live by one's self under such, even self-imposed conditions, at times having to go days with only bread and water, or with now and then the addition of an occasional dinner at a restaurant when by chance an extra fee came in, and this for months, was had enough; but to feel obliged to "hold the fort" continuously, day and night, that nothing escape through absence, depriving one's self of all social or other needed recreation, became much more unbearable. The French have a saying that there is no necessary man, and I began to think that I was indeed the very individual the adage referred to.

Occasionally a friend would come in, and, by way of consolation, suggest that a calling which did not immediately *pay* was not worth following up.

A notable family once sent for me. They had sickness in the house. Their family physician, they said, had become old and so infirm that they felt obliged to give him up. They had long known of me and of my abilities and standing; had great regard for me, and they felt, in this serious emergency, that they could confidently trust in me — to tell them whom they had better employ as their physician. Keeping my self-possession as best I could I told them, without apparent hesitation, whom I would send for were I ill myself. They sent for him, and he ever after attended them.

I had saved a trifle from my allowance for student expenses, and only a few coppers remained, when a lady called me to her assistance. She was found to have a mammary scirrhus. After proper consultations with higher authorities it was decided that the organ should be removed. One day she took me aside, and, with great solemnity, asked me to tell her, upon my *honor*, whether I thought that I could do the operation *well*. She did not ask me, she said, to say as well as the eminent gentlemen who had seen her, but *well*. On my answer in the affirmative, she told me to come prepared to do it on the following Tuesday. Remember that there was no anesthesia then. It required several strong persons merely to hold a patient, writhing and groaning, during such an operation. The operator, then, could not loiter to determine uncertain tissues. He could not stop even to tie up arteries, unless very important ones. He was obliged to go rapidly on, and to receive unmoved jets of blood in his face, or wherever they might fall. Yet he did not think it advisable to wear the butcher-like frock now sometimes seen, or to embarrass and poison the proceedings by foul-smelling vapors or poisonous washes.

More than one of the assistants whom I invited (but not the aforesaid Professor of Surgery who kindly offered to be present and assist me), suggested the consequences of failure; but the operation was performed, and to the satisfaction of all. This was my first case after graduation, and it required some firmness of purpose to meet its exigencies. I am happy to see here present a gentleman,⁶ the friend of my earli-

est youth, who was with me and assisted in the operation I have just described.

While I was attending this patient a gentleman called for temporary advice, and insisted on paying a fee. It was the first payment for professional service, and the hesitating reluctance with which the amount was named and accepted is well remembered to this very hour. The service rendered did not seem to me worthy of any compensation — a common experience, I believe, with young beginners. The bank-note thus received (the smallest denomination then issued), was never parted with. It still hangs in its frame by my books, a constant reminder of the sensations it at first aroused.

But a few patients, however prominent, do not make a practice. This I well knew; and I had not taken a place among active practitioners with any intention of remaining permanently in the city. The truth was that, although I had had an unusual amount of actual practical experience for a student in those days, especially in obstetrics, through my connection with the House of Industry, I was still in a formative stage. At the House of Industry during my charge of it as *Interne*, besides a very large number of patients constantly in the wards with all sorts of diseases and ailments, including insanity, there were over thirty births and one hundred and fifty deaths. Thus an opportunity was afforded for the study of disease in all its forms and terminations, from earliest infancy to extreme old age. There, too, were many chances for autopsies, dissections, and operations on the subject.

A little knot of us students (I believe that I am the only survivor), had been in the habit of meeting together to report cases, and to *quiz* each other's work, criticising in, sometimes rather roughly, in diagnosis, prognosis, and treatment. In like manner we assembled for operations at the dead-house. The subject having been put into position, one would take the watch, for rapid action in those days was second only to thoroughly skillful performance. The watch-holder would call upon one of the others, at random, to do an operation then for the first time named. When finished the operator was subjected to the relentless criticisms of the lookers-on, who never failed to find some fault or omission, or to suggest some improvement. These and similar exercises were the source of incalculable good to each and all of us.

It was then the custom also, at the college, for students who were willing to be examined on the previous lecture to take the front seat in the lecture-room. Generally there would be half a dozen or so in this seat, though only two or three of us took places there throughout the whole course. We thought it better to fail there than to prove ignorant afterwards when ignorance might be more disastrous. Many corrections of unsuccessful replies were fixed firmer in our memories than our correct answers.

Notwithstanding all this, and perhaps in consequence of it as it showed our limited acquirements, I felt far from competent to assume at once on graduation "the responsibilities of a general practitioner" alone and unaided, especially in a country town to which I seemed destined.

Though constantly on the watch, the looked-for "opening" did not show itself to me. Determined to make but one move, and that for a permanent location, I staid on, attending additional lectures, "walk-

⁶ W. W. Wellington, M.D., etc., of Cambridgeport, Mass.

ing" the hospital, then the only one, the Massachusetts General, practising as I could, "getting up nights" for neighbors (always giving up the patient in the morning to the regular attendant), and bleeding for others in order to save them the trouble, and to become, as was then considered important, adroit in the performance of that frequent operation.

I made autopsies also, and I may interpolate here that I once gave up a lecture to make a post-mortem for a gentleman who left his patient apparently moribund the evening before. On our arrival the patient was still alive, and, more than that, subsequently recovered. The doctor lost the patronage of the family, and never afterward arranged for an autopsy unless sure that it would be a *post-mortem*.

So, too, I assisted in surgical operations whenever and wherever I could get the chance, adjusting dressings, cleaning up, etc., etc., in short, seizing (without expectation of pay), upon every opportunity of the kind that fell in the way. In those days beginners were thankful enough for any chance to gain experience, in order to become qualified to practice satisfactorily when established for themselves. Things seem much changed nowadays. According to some recent reports it is not always safe to ask a "young doctor" to take care of a poor patient unless prepared to pay the bills. And, improbable as it would appear, not long ago a lawyer's dunning letter was sent to a physician at the instance of another practitioner who had attended a non-paying patient of the former during his temporary absence.

Some of my college classmates, fellow medical students, went abroad. I saw the advantage of such a course, but was not able to follow their example—fully aware that no amount of application at home would, at that time, give the prestige of a short residence in a foreign capitol. Nowadays by its frequency, and by the increased advantages and the better teachings at home, this foreign service has become, in the way indicated, of much less importance.

Thus I held on, getting little but work and experience; enduring a real "famine," and *voluntarily* accepting privations such as young men of to-day would hardly credit were the half only told them. The experiment was indeed a severe trial in its daily demands on patience and fortitude, but it has proved of valuable assistance in inducing more appreciative views of human exigencies; and its "sufferings" now appear supremely trivial beside the many tragical struggles for existence which the profession daily calls one to witness. It showed too, that one if so resolved, or necessitated, can keep up appearances and live at as little cost in Boston as anywhere in the world.

After a while I could pay for a regular dinner, and obtained it of a worthy person, who, occasionally a patient, kept a boarding house in a distant part of the city. This also daily gave needed diversion from otherwise strictly professional pursuits. The distance also answered the intrusive question why all the meals were not taken at the same place.

Occasionally an elder practitioner would send a paying patient—a valued recognition, much needed and gratefully received.

After a year or so I obtained what I had at first sought, a room on the street-level in Winter Street, becoming the twenty-fifth practitioner on that short street.

Just before I left Washington Street a singular case

happened in the house where I had my office. An elderly man, afflicted with rheumatic and swollen limbs, requiring, as he thought, frequent applications of liniments, had been bathed at night-fall with an unusual quantity of alcohol and spirits of turpentine. On the approach of an attendant with a lighted candle the whole took fire and enveloped his limbs and lower part of his body in a sheet of flame. Though the blaze was quickly smothered the shock was too great, and he died in great suffering not many hours afterwards.

In Winter Street, quarters were somewhat better, though plain enough compared with modern requirements. Here I lived in the house. I added to my furniture a plain book-case, which at an auction cost me a couple of dollars, and I arranged my cot to be turned up in the corner out of sight in the day-time, as I still had but one room. Here I remained until I removed from the city.

While I was on Winter Street, Dr. Hayward, taking a vacation of six weeks, asked me to remain for a time at his house and attend to his patients. Afterwards he generously gave me all the fees as they were from time to time collected.

President Quincy sent to me under-graduates who were required to "make up" studies during their vacations. For hearing their allotted tasks, which caused me to review my college studies, I received compensation which greatly increased my very small pecuniary income.

A word for the rocking-chair. When Mr., afterwards Sir Charles Lyell, the geologist, first came to this country to lecture, I was temporarily curator of the Lowell Institute for my friend Doctor Jeffries Wyman, who then held the office. Mr. Lyell, who was a tall and undulating person, came to my office one morning, and, throwing himself into the chair, began to rock it quite violently. As he was uttering the words "we don't have such luxuries in England," over he went, smashing the chair to pieces. With hearty roars of laughter he pushed the fragments aside, and continued his visit, sitting on the floor with his hands clasped about his knees. As long as he lived he never escaped occasional questionings in England about his experience in American luxuries.

I was now getting a little more prosperous. I had also by this time collected a few more text-books—new works and monographs of the day—mostly at auctions which students frequented. Among the books was the new Forbes, Tweedie and Connolly Cyclopaedia, in four volumes, large double-columned 8vo, which was then thought to be so complete that nothing further would ever be required on the subjects of which it treated. Yet who ever hears of the work at the present day? But very few beginners, I imagine, then bought many books or set up large libraries.

For periodicals, I was permitted to join a Reading Club which took all foreign and domestic medical journals. Several physicians having large libraries offered the use of them. I was appointed librarian to the Medical College, which, besides putting my name on the annual announcement, and giving at all times free entrance to the college, required me to take care of its rather limited collection of oldish works; to be present every Saturday afternoon to loan books to such students as wished to borrow; and to keep posted so as to assist searchers in their investigations. I was one of the earliest subscribers to Braithwaite's Retro-

spect, which began as a very small and thin duodecimo. Its first volume, which I received in advance, contained an abstract of a paper on "the use of *Oil of Codfish in Scrofula*," setting forth most wonderful results. This paper came under the cognizance of an apothecary's assistant, who (having had a difference with his master and set up for himself), determined on the strength of its alleged virtues, to try "*a run*," as he called it in telling me, on the article; little thinking, however, what a marvelous "*run*" it would become. "*Cod-oil*" was not a new thing as a medicine. I had tried it, but could seldom prevail upon patients to take any considerable amount of it. Newly started abroad, however, it was extolled and swallowed here *ad nauseam*. So much of the vile stuff did doctors pour down their patient's throats, and the people take of their own accord (for any and every disorder, after it had become fashionable), that the price of "*fish-oil*" in the market soon went up more than five-fold. As an example of the extremes to which fashion may lead even educated practitioners, a plump and pleasing, hectic-cheeked young woman was pointed out to me at an assembly, by her physician, as an instance of restoration to flesh and health by taking, he said, "more than a hog'shead of cod-oil." Extravagant language this, but not more extravagant than the reports of some of our most prominent practitioners at the time. The young woman died a few months after she was pointed out to me, in spite of the published cure by the "remedy."

Little is heard of the article now except in some mixture or emulsion to make it go down with the public.

But if few beginners bought books, fewer still collected many instruments. Surgery was not the comparatively easy thing, without ether, that it now is with anesthesia; and not so many then aspired to become operators. I had endeavored to qualify myself for the surgical emergencies of a country practice, where one must rely chiefly on himself and be ready to act at once or suffer in reputation, if the patient did not suffer in life or limb by delays attendant on obtaining a bolder if not an abler practitioner.

I had, of course, my common dissecting case. A German, Leitz by name, for some service I had done him, had made for me, while a student, several delicate instruments for sub-cutaneous tenotomy, and for strabismus, new operations in which, even then early, I had become quite expert. One of my teachers gave me a scalpel, an Evans, with which I performed my first operation after graduation, and my last a short time ago. It has been a much-used instrument, "my good English knife," as Dupuytren is said often to have exclaimed, holding up a favorite instrument. I had free access to an instrument-maker's armament, in consideration of many suggestions I gave him. I had also a present of tonsilotomes from the designer, and, from the same source, an amputating case, all the contents of which, I am sorry to say, I was (contrary to prediction) obliged subsequently to use, even the long ten-inch double-edged catting, in an amputation at the hip-joint. The saw of this case was a common carpenter's saw, fine-toothed, for hard wood. It was selected by myself, and fitted up with an ivory handle. The teeth of ordinary surgical saws are too raking for dividing bones readily.

Of course, as I went on, I obtained such books and instruments as were essential to immediate exigencies,

but from the start I was often obliged to follow Baldwin's dictum⁶ and use whatever came to hand as best I could. "A wooden *bicker* or bowl" for a compress in a desperate case, by a "rough and ready lad," is mentioned by Dr. John Brown, of Edinburgh, with high approval in his "*Locke and Sydenham*," pp. xi-xii. So, too, an iron spoon for a vectis, as used by a late member of this Society in an emergency, is worthy of commendation.

I had waited patiently in my Winter Street office, but at length the long-wished-for day came. While I was musing on hope deferred, and anxiously looking up a place, the fire was burning. Two of my former medical teachers, without concert or knowledge of each other's purpose, called upon me the same day and set forth the advantages of Roxbury.

I had long known its woods and pastures in botanical excursions, in which I collected specimens for the wild-flower corner of the Massachusetts Horticultural Society's weekly shows. From these gatherings remain some five or six hundred varieties dried and preserved, in suitable volumes, most of which are now in the possession of one of our professional neighbors. Moreover, I was not wholly unknown to some of its prominent citizens. I had, however, strange as it may seem, never thought of it as a place of residence, but a walk thither (street-railways were not, and stage fares were too much for the impecunious) soon determined the matter. One look was enough to take in the situation. In less than a week a location was selected, and a full practice begun.

Roxbury then had six regular physicians in active practice, and five or six more "doing a little something." There were two irregulars also, one of big and one of little pills, together with several medicine vendors of no great importance.

Among the first-named was an old practitioner, a thorough regular, who attended quite a number of the oldest families. He took a fancy to me, and gradually transferred these patients to my care. He had a pill, which he valued much, and which (though a formula of much older times) went by his name.

One day he hailed me in the street, and asked me whether I knew of his pills. I replied that I had heard of them. "Oh," said he, "they are invaluable — just have a pocketful always; and when people come to you with their long stories, and *you don't know what to do*, give them from your pocket" (suiting the action to the word, and bringing out a handful loose from his own) "give them half-a-dozen of my pills, and that will do the work for them. *Always keep a pocketful of them by you!*"

The fees then were very small, and, although a more expensive place to live in except in house-rents, it is a few years only since they were in reality raised to a limited equality with those in Boston proper.

As to getting about town, the main roads were pretty good for a country place; but the sidewalks were mere earth-paths along the travelled ways. There were no curb-stones. The streets were not generally lighted at night; never when a moon was expected to shine. Lights on vehicles at night were a necessity, and lanterns had to be carried by pedestrians. Rubber boots had not been invented, and heavy, well-oiled cowskins were a burden in the mud of stormy times, and hardly kept the feet dry. South of Dover Street there were a few houses only. Tremont Street was a

⁶ See Boston Medical and Surgical Journal, May 19, 1887, p. 480.

mere road, raised but little above the marsh. It was lighted as other roads were, with oil lamps, few and far between; and the lighting of "the Neck" with gas, years later, was a notable event. There were but few chances by the roadside to tie a restless horse, and I was one of the first to adopt the weight (now commonly used), invented by a brother physician,¹ affixing an iron hook or snap instead of a buckle, the original means of its attachment to the bridle. The risks and fatigues of night-service can hardly be imagined by later beginners.

Roxbury then had about nine thousand inhabitants, but was beginning to increase rapidly in population. Now it is said to number more than seventy thousand. It was at that time, to me, a beautiful suburban town, not much less distant from Boston, in time, and not much more accessible than Worcester now is. Now it is, unfortunately, a "Southern District" only, as the law calls it, of a large city, and subject to all the inconveniences of such a relation.

Of my practice in Roxbury, I may say here as well as anywhere, that it was very much larger than I had ever dared, for a moment, to anticipate for myself there or anywhere else. This result was due largely to the unsought and very cordial expressions of goodwill and confidence of the Professors in the Medical School, and other eminent medical gentlemen of the city, who had observed my course as a student, or had witnessed my solitary talent, if I had as much as that, namely, a talent for *work*.

This practice, at times too large for one person, I think I can truly say I was never unwilling to share with others, especially with younger men or newcomers, struggling in their first efforts to get a foothold. I always felt impelled to this in remembrance of my own early struggles, and of similar assistance when most needed. For doing thus, all I ever asked was that the recipients should pass similar favors on to their successors. I never expected nor have I ever received commission or personal favor in compensation.

On the whole my practice, with such increase as naturally follows faithfulness to employers, was at first derived chiefly from new-coming residents, the patients of others voluntarily sent to me and from practitioners relinquishing business. Thus my success has been largely due to the profession's partiality; and I have tried to repay in some humble measure the great obligation.

My actual service has embraced all classes from the highest to the lowest; and for many years gave no time for rest day or night. I never added up monthly or yearly *charges*. Generally, once a year, each patient of supposed ability received an enclosed memorandum of his indebtedness, usually not made out by myself; and he was left to pay at his leisure. A plea of poverty never failed to secure a withdrawal of my claim. Some, who should have answered, never responded; and thus arose the saying that I own several undivided shares of houses, paid for in part (if paid at all) by fees withheld when they should have been rendered unto me for services. Seldom, however, have I been thus overreached by any who have not similarly endeavored to wrong others in their several occupations. On the other hand, many in course of time paid, whose indebtedness I had entirely forgotten.

This plan of mine has worked well with other prac-

tioners who adopted it at my suggestion. One can act independently if he does not know or remember that the applicant owes him money; and it is no harm in the long run to have many debtors for acts of unpaid kindness thus rendered to them. I tell young men to make as many such debtors as possible, thinking less of payment than of service.

As a whole, I do not suppose that a half of my work for those apparently, but not always really able (not including "charity" or "dispensary" patients so-called), has received pecuniary compensation. The rich, too, often exact more than they are willing to pay for, still, one cannot be a very large-hearted practitioner who does not find out at length, in self-satisfaction at least, "how much better a half is than a whole" — especially the gratuitous or unpaid half!

The practice of medicine must be very disappointing to those who follow it chiefly for the acquisition of wealth. Whoever practices it in a commercial spirit debases the calling and degrades himself. As a French writer has truly said: "Medicine is the noblest of professions, but the meanest of trades."

Some classes have seemed to think they are entitled to a physician's service as a matter of course, though no reason can be given for it. Formerly, clergymen were considered such beneficiaries. One year I attended eleven clergymen's families, most of whom received a larger income than myself. I felt obliged to exact payment of those not connected with local parishes. It is customary now, I believe, not to make even such exceptions. More than this, fees are now sometimes charged for attendance on brother-practitioners, or, if not charged, a liberal honorarium is readily accepted for such service. I never took a fee from a female teacher in our public schools nor often from males in the lower grades. During the war, I examined, gratis, the companies of recruits assigned to me. I also attended, as in the other cases alluded to, without public or private announcement, the sick and the wounded officers and men from generals and admirals downward, and their families, without charge or compensation.

The greatest number of professional visits to separate houses I ever made in one day was forty-three (a few of the houses visited having more than one patient). It was one of the longest days of summer, and there was no time for rest, from early dawn to late at night. I once attended four births, in different parts of the town, within twelve hours; between twelve at night and twelve at noon following. It happened to be a February 22d, and the three boys were each called George Washington, while the girl received the name of Martha. The mothers were unknown to each other.

On one occasion, a father wishing to weigh a very large child, sent Bridget for scales. She brought a small pair. "Those will not do," said he, "they are not half large enough." "Oh," said Bridget, "then put 'im in twice."

I had, indeed, a full share in obstetrics. On the first of January following the April of my coming to Roxbury, I had on my list thirty-seven obstetric engagements. During the year following that date, I attended ninety-six cases; during the next, one hundred and fifteen cases; and so on, until I had a very large fraction of the whole number in the town.

This department was never satisfactory to me, nor do I deem it pecuniarily profitable, although the fee

¹ The late Dr. John B. Brown, of Boston.

is considered large. If all the extra calls now usually demanded, and the wasted time were paid for, at average rates, without the lump-fee, the attendant's compensation would probably be greater than now; and the patient's family would not be so exacting of the physician when he was not actually needed.

I had been early put to my trumps in this department. When I had hardly finished my second year's studies, and when I had only imperfectly "assisted" by being present part of the time at two deliveries conducted by others, I was residing with a prominent Boston physician and was sent one dismal night to a distant residence to "keep the patient" until the doctor could reach the place, he being at the time in attendance on a similar case afar off in the opposite part of the city. The patient I was to "keep" was a young woman in her first pregnancy, who had come from the country to a friend's house, to make purchases for the event, expected some weeks later. I had not reached the place too early, but on entering the reception-room I was plying with numerous questions, rapidly put to me, chiefly as to qualifications and experience. While I was getting "very red because so very green," I put myself on the negative defensive; I would not force myself upon them; nor stand in the way of any other arrangement. I was sent to save them from any mishap, and probably would not have been so sent if thought incompetent. I added that I had no objection to their sending for another practitioner (inwardly I wished they would do it), but would remain only until they had procured one to their liking. Meanwhile a conference was going on, aside. Their messenger had left. The darkness and storm outside were appalling. In their ignorance of their professional neighbors, a hap-hazard choice might be worse than taking the one present, who, at least, had their own doctor to fall back upon. At this point, the urgent calls of the nurse interrupted their consultations; and I was hurried up into the patient's room. Suffice it to say that all went on happily, and I reached my friend's house at early dawn, before he himself had returned. I had told the family that the doctor would visit them during the day, but they replied that there was no need of two physicians in the case, and wished me to continue attendance. Accordingly the doctor drove me to the corner of the street and waited for me in his chaise while I visited my patient. This he repeated as the case required. All this happened in one of the doctor's "first class" families. He never saw the patient, but he charged and received a "first-class" fee. I had the experience.

The procedures in the lying-in room were then somewhat different from the present. The bed usually consisted of two sacks: one of feathers, the other, underlying, of straw. The upper was folded half up on itself, and the patient was placed across the exposed half of straw. After delivery, she was made to stand up, and, while the soiled clothing dropped, clean and fresh garments were slipped on her from above. She was then lifted up (by the doctor if he was strong enough), and placed in the bed, which in the meanwhile had been readjusted by the nurses. Thus "in the straw," and "putting a woman to bed," had a greater significance formerly than now.

adays. We, when youngsters, altered all that long ago. The patient, now, on a comfortable mattress, from which she is not to be removed, taking the position she pleases in an easily-detached dress, supplied with scores of napkins readily managed and quickly removed, passes neatly and with comparative facility through the ordeal.

For some readers, I may add that I never could see the philosophy of "supporting" the perineum, so-called; on the contrary, the plan usually recommended seemed to furnish a fixed point whereon to start a rent. Therefore, I have never done anything of the kind. And, as to ruptures, I am confident, the fact is that I have not had one in a hundred cases, never a bad one. The number of times that I have taken a stitch for real or supposed necessity, does not amount to half-a-dozen. To be sure I have not used a candle for visual demonstration, but I have always ascertained the condition of things by digital touch, adequate I still think, as the placenta in passing puts the parts upon the stretch. In the management of such matters I never had any other rule than to relieve extra pressure as circumstances demanded.

Before the idea was started that puerperal fever may be communicated, I was once in attendance on four cases of this disease (two, however, not until the fever had begun), while I attended eleven other patients without any injury to them. Once I attended a patient in the next bed to a puerperal fever case, and no harm resulted, both patients having the same nurse. In an epidemic of this affection, I have seen cases clearly indicated days previous to delivery. If ever a consecutive number of cases of this disease occurs in the practice of one physician, while none appear in that of others, the same is true of other diseases. For instance, I have known this to happen with scarlet fever, where "carrying" by the attendant was out of question, as he went to the patients only after the disease had manifestly revealed itself.

In fact, in spite of what non-practising theorists allege, I have never known of a case of this affection to have been unmistakably carried by an attendant, however much exposed he himself may have been. Various other theories explain such matters much better, if we cannot acknowledge our ignorance. Epidemics will prevail, and often confound the wise by their strange and unusual courses. The same may be said of all the portable diseases so-called. Thus it seems to me, and I have had some chance to learn of these matters at home and abroad. At any rate, the unnecessary alarms, so often carelessly raised, are more damaging to a community than any such portability was or can be. Witness, on a large scale, London's ordinary amount of scarlet fever, sensationally misnamed "raging,"⁹ the recent call for "red flags" in our own neighborhood, and the present "fright" (as we may now add) in a country place in another part of the State, where with less than a score of cases in four thousand inhabitants, according to the papers, "the town is greatly excited, and the authorities are blamed for not being more active in checking the spread of the disease." It is hard to be reconciled to the inevitable, the unavoidable — somebody must be blamed.

Of the incidents and experiences befalling me after settlement in Roxbury, some were certainly peculiar, others of a somewhat serio-comic character, of which one or two instances may be given in illustration.

⁹ I once knew a physician who acquired quite a large obstetric practice chiefly by being strong enough to take the patient up at arm's length and thus put her gently into her bed unassisted.

⁹ Lancet, November 26, 1887. p. 1073.

I happened to take with me Desault's apparatus for fractured thigh. The reputed surgeon of the place (Dr. F. Brown), who was on the point of removing from town, often made me friendly visits. Seeing this apparatus one day he declared it to be perfectly superfluous; that I had better make firewood of it at once; that there never had been but one case suitable for it in the town, and that that was hurried off to a hospital before a local doctor could reach the place of the accident.

A few days only after these remarks two cases of fractured thigh, within twenty-four hours of each other, occurred hardly a stone's throw from my residence. The one required my Desault, the other all the wit I had to construct suitable appliances from materials at hand.

An amusing incident occurred in connection with these accidents. As a large and full omnibus left its station, at the head of it sat a consequential individual, a self-constituted "boss" of local matters, and a would-be magnate of the town and vicinity. Overhearing a passenger at the other end of the vehicle relating the affair as they passed the place of the accidents, he loudly called out in a rough voice, "Who'd you say attended them?" On being answered "Dr. Cotting," again exclaimed. "Dr. Cotting! who in hell is he?"

I took the first opportunity to render a gratuitous professional service to his family, that he might recognize me as a near neighbor, call the place in which we lived by whatever name he chose.

My extemporary apparatus, somewhat improved upon and used afterwards in preference to any other, I published an account of in the *Medical Journal*,¹⁰ and, as a supplement, a description (both with woodcuts) of a "fracture-bench," so called, devised for his son by Dr. Monroe, a member of the Norfolk District Society.¹¹ Subsequently in repeated instances I found this "bench" easily set up and very useful.

The following season, on a Saturday afternoon, a master-mechanic, a very large and heavy six-footer, exceedingly muscular and strong, dislocated his shoulder. His physician made half a dozen or more attempts to reduce it. The patient suffered much, and roared lustily in the process. The parts became very sore and he very impatient, calling loudly for other assistance. I was stopped in the street by a messenger and taken to the place. I was told by the medical attendant of the attempts he had made, and that I might try *my luck* if willing. The extension made had been irregular and spasmodic, and I noticed a failure to fix the scapula.

Attending to this latter point, and putting several strong men on the arm that the extension might be slow, steady, and relentless, in less time than it takes to tell of it the reduction was effected, without apparent pain to the patient. Shouts went up outside from the crowds of workmen (it was pay day), and others gathered in the street, who thus and otherwise, quickly noised the event throughout the town. On my leaving the patient in his hands the doctor remarked that his previous efforts had probably relaxed the parts and rendered the operation easy for me. I accepted the explanation, but he never forgave me for my success.

A few weeks later I reduced, by pulleys, a dislocated shoulder of several months' standing; then, with-

out ether, a difficult not to say somewhat hazardous operation. It was deftly done, but I never heard mention of it outside the house wherein it occurred. So disproportionate, often, is fame to the merit of the service performed.

With such a start it is needless to say that for years after I had all the casualty surgery of the neighborhood that I was inclined to undertake. The building of the City Hospital brought a great relief to me in this laborious and generally ill-required work.

On the union of Roxbury with Boston, even before its full consummation, I was especially offered the place of attending surgeon in the hospital; again a year or two later, and once more after that: *thrice*, and *thrice* I declined. I have been accused of unwarrantable ambition. "Was this ambition?"

I have, however, held the position of consulting surgeon to the hospital, an honorary office, for now nearly twenty years.

I could tell of a register case, a true story; but strange, in faith more passing strange than the fiction on which Mr. Howells founded his popular little drama of that name. It was in short, an unwarranted fabrication by a listener at a register, who "didn't hear the consultants say anything about the patient!" But for a little forbearance on my part the story and the unavoidable defamatory inferences might have become a serious matter to the listener.

SOME OF THE OBSTETRIC AND LEGAL RELATIONS OF INFANTICIDE.¹

BY F. W. PRATER, M.D.,
Assistant Professor of Legal Medicine in Harvard University.

In the proceedings of a body whose organic character and purposes are mainly devoted to the preservation of infant-life during its transition from the foetal to the personal stage of existence, any discussion of the method and proofs of the criminal destruction of that life is certainly novel, if not incongruous. Yet I venture to ask the indulgence of an Obstetrical Society to a brief consideration of a theme greatly out of its ordinary course, but having, nevertheless, obvious obstetric relations. The puerperal primipara and the new-born child are sufficiently familiar objects, under the frequent observation of the practitioner of midwifery; he gives to them his best care, tenderly, skillfully and safely guiding them through the ordeal, long awaited, patiently endured by the woman whose normal maternal instinct finds in the welcome first cries of her child abundant recompense for the pangs attending its birth. In the tragedy of infant-murder, too, as it is usually presented to us for study, the actors are the same: the puerperal mother, who is the active agent in the affair, and her child, just born, the easy victim of her unlawful act. The ever-marvellous mechanism of parturition is here again repeated, presenting no new features save in its surroundings; but in these, the contrasts at once appear which make an affair of child-murder a matter of novel interest to us. The physician's skill has no place in this lying-in. The throes of labor are borne in secret. Nature unaided and unguided accomplishes the delivery.

¹ Read before the Obstetrical Society of Boston, November 12, 1887.

¹⁰ Boston M. and S. Journal, Sept. 19, 1861.

¹¹ Ibid. Feb. 13, 1862.

There is no tender sympathy of kindred or of friends at hand, no trained attendant to comfort and encourage. It is obstetrics reduced to its simplest terms.

How women behave under these conditions, what powers of endurance they exhibit, what methods they adopt to conceal the fruits of their illicit indulgences out of wedlock, and what evidences we seek in the dead bodies of their new-born offspring to convict them of the criminal destruction of human life, it will be the purpose of this paper to illustrate. I offer the following notes of cases occurring in my experience as a medical examiner, as the most fitting introduction which I can present. From a considerable number of affairs of this class, I have selected two only, regarding them as typical examples of their kind; having in mind, also, the obstetric relations of the subject and choosing, therefore, the cases in which the mother, just delivered, was clearly shown to be, or with good reason was suspected of being, criminally responsible for the death of the child. During the past ten years, I have been summoned to inspect the dead bodies of two hundred and thirty new-born children, in all stages of fetal development, found in all sorts of places (privy-vaults, ash-barrels, snow-heaps, the shores of tidal or river waters, in back-yards and vacant lots) and presenting a great variety of anatomical appearances more or less indicative of violence as the cause of their death. How they came to be thus unceremoniously disposed of and whence they came, could only be conjectured in most instances; no clew to their origin accompanying them, they became the subjects of barren medico-legal investigations.

CASE 1. Kate D., a healthy, unmarried Scotch girl, a primipara, nineteen years old, was charged with killing her new-born child under the following circumstances. In the last week of December, 1886, she undertook service as a cook in a small family in the suburbs of Boston. Her employer noticed the suggestive contour of the girl's body but kept her suspicions to herself. February 11th, on her return home after several hours' absence, Mrs. A., the mistress, found Kate in the kitchen, suffering from "cramps" which were declared to be due to menstruation, just then recurring after many months' suppression. Kate was sent to bed and was advised to apply hot cloths to her abdomen. Next morning, the girl was found at her usual place in the kitchen at five o'clock. She said she felt better and expressed her purpose to do her work as usual. She looked ill, however, and Mrs. A. sent her back to bed, where she remained through the day. On the 13th (Sunday), she was up and dressed, but spent much of the time on a lounge. That afternoon, Mrs. A. by some chance happened to look down into the privy-vault, which was situated at the extreme end of the dwelling-house premises, and there discovered lying on the frozen contents of the vault, a bundle of white clothes. Taking it out, she found satisfactory evidence to confirm her surmises of the true nature of her cook's sickness, for the bundle contained the body of a new-born child. A physician was now called, who upon examination, found additional proof of recent parturition in the condition of the external genitals and in a small recent laceration of the os uteri. His patient repeated the story that her illness and flowing were due to menstruation, and the doctor, for good reasons, permitted her to continue her deceit without informing her of the discovery of the child in the vault. Her pulse and temperature were normal

and her puerperal condition gave absolutely no ground for anxiety.

Next morning, answering the physician's summons, I had an interview with the girl in his presence. With the utmost coolness and unconcern, in reply to my request that she would tell me just what had happened to her the previous Friday night, she said that she was taken flowing and that was all. When informed that her child's body had been found and that all of us knew that her sickness was the sickness of child-birth, she changed her confident tone and, after an outburst of tears, described her lying-in. She said that her pains began about six o'clock on the Friday evening; she supposed them to be her "turns" coming again. She declared that she did not know that she was pregnant, although she had twice been imprudent with her lover, whom she had left the previous June in Scotland. She had never told any one about her suppressed catamenia, and had not made any baby-clothing or other preparations for child-birth. At about three o'clock in the morning, while she was alone in bed, in her room, the baby came. She did not hear it cry or feel it move; she thought it was dead when it came. She got up in five or ten minutes after the child was born and went downstairs, through the dining-room, kitchen and laundry to the privy, and there something else came away from her. She took the baby down with her, and put it down the vault. She did not hurt it in any way during the birth and did not put her hands on it till she took it up to remove it. The navel cord broke when she arose from the bed.

Such was the girl's story. The anatomical appearances of the child's body did not fully correspond with it. In some regards, however, there was entire consistency. Her prolonged menstrual vacation was confirmed by the mature fetal development of the child; the weight was seven pounds and seven ounces; the length was twenty and a half inches; the hair measured an inch and a quarter in length and the nails extended beyond the tips of the fingers; there was a centre of ossification in the lower femoral epiphysis, of the size of a large pea; the pupillary membrane had disappeared.

The account of the time, progress and result of the labor was likewise corroborated: the funis was fresh, its length was eleven inches and its end was torn and without a ligature; the skin of the groins was smeared with fresh *vernix caseosa* and the face, neck and shoulders were blood-stained; there was no *caput succedaneum* to indicate a tedious labor; the skull-bones were freely movable; the colon was full of meconium throughout its length.

Beyond these two particulars, the mature development of the fetus and its recent birth without accident or delay, the young woman's declarations and the post-mortem condition of the child's body did not agree. She avowed her belief that the child was dead when it passed from her; opposed to this avowal were several facts in anatomical evidence. The lungs were expanded so that they nearly filled the pleural cavities; their color was pale gray, with a reddish tint; they crepitated distinctly on section and under pressure; their edges were rounded; their lobular boundaries were distinct; placed in water, with the thymus and heart attached, they floated high above the surface; cut while held under water, they emitted bubbles of air freely; each lung, each lobe and small sections of each

lobe floated freely in water, both before and after firm compression. The bronchi contained blood-stained froth. In the stomach, there was a mixture of air, mucus and free blood. In short, we found ample indications that air had been freely admitted to the lungs and stomach, before the child's death; while the body presented none of the appearances of still-birth and no abnormality to occasion that result.

The mother's statement, too, that she did not touch her child until, finding it dead, she took it in her hands to remove it from the bed, was radically at variance with the many signs of violence which the body presented. Externally, there were ecchymoses above and between the eyes, on the right cheek, within both lips and on the left side of the neck. There were abrasions and excoriations, of various lengths and widths, on the forehead and nose, and (most significantly and numerous) on each side of the neck, four on the right and seven on the left, linear and superficial, oblique in direction and from an inch to a sixteenth of an inch long.

The right humerus and right radius were broken.

Upon internal examination the body presented further proofs of a violent death during, or immediately after, birth. Dissection of the neck demonstrated widely extended bruising, the parts being infiltrated with blood, on the left side from the clavicle to the parotid gland, and on the right side over a more limited area. Under the scalp, frontal and occipital, there were ecchymoses. The periosteum over the parietals was raised from the bone over a space an inch square, by a sub-pericranial effusion. Both parietals showed fissures, the left an L-shaped crack extending from its edge downward and forward, the right, a linear fracture an inch long, extending directly downward toward its centre. The brain was very soft, with more than ordinary injection of its meningeal vessels, but without sign of laceration or bruising of its substance.

The superficial vessels of the heart were fully injected. The blood was thin and dark. Its distribution in the cardiac cavities was not remarkable.

There were subpleural ecchymoses of both lungs, varying in size from that of a small pea to that of the little finger-nail. No punctate ecchymoses were found. Upon section the lungs displayed numerous dark red areas of hemorrhagic extravasation, appearing as spherical or irregularly-shaped minute nodules, distributed equally in the two organs. The tracheal and bronchial mucosa was reddened.

These post-mortem appearances left but one reasonable conclusion, namely, that this child came to its death by the acts of the mother in her continued efforts to conceal the results of her amatory imprudence. That she was not as innocent or as ignorant concerning the true nature of her "cramps" as she professed, or as unconscious of the relation of causes and effects in her condition as she pretended, is shown in her neglect to call for the help of her mistress during the closing stage of her labor pains, while her repeated and fearful questionings relative to "what they would do to her" suggested strongly that her faith in the credulity of her story of the still-birth of her child was not absolutely unshaken. She was removed to the Boston City Hospital for puerperal convalescence. She remained here a month. With the exception of an attack of diarrhoea, which occurred three weeks after her admission and just as she was

about to be discharged, the convalescence was without complication or noteworthy incident. In due time the wheels of the judicial machinery of Massachusetts began to revolve about her case with becoming deliberation, and the result of it was that the grand jury concluded not to indict her.

CASE II. Josephine J., an unmarried woman about twenty-five years old, left her home in New Brunswick about the first of February, 1883, and came to Boston to meet the crisis of her lying-in, then impending. The father of the unborn child paid a part of the expense of the journey. The date of the impregnation was the previous June. The woman found a place at service and awaited coming events. At 5.30 A.M. February 24th, Josephine called her mistress, who found her suffering the characteristic pains of the first stage of labor. The matron remained with the maid for about three hours, watching the progress of things, and applying simple remedies, suspecting, without declaring, the true nature of the attack. After her mistress left her, the case proceeded as follows, according to Josephine's statement: At nine o'clock the child was born; she had felt its motions before its birth and afterwards, and she knew it was alive, although it did not cry. She broke the navel-cord and laid the baby on the outside of the bed. In about half an hour the after-birth came away. She then dressed herself, left the child on the bed, and went down stairs to the kitchen where her mistress was. The latter continues the account of the affair as follows: Josephine looked so badly on coming into the kitchen that she accused her of giving birth to a child and attempting to conceal the act; this charge Josephine denied, but presently, upon its reiteration, she admitted its truth, declaring that the child was dead when born, and adding that she had placed the body in a drawer in her bedroom closet. Going to the bedroom Mrs. G. found the child in a closet-drawer, but it was not dead. The drawer was shut. The child was breathing with difficulty, and Mrs. G. noticed that the mouth contained some white object which held the jaws open; upon removal this proved to be a piece of newspaper loosely crumpled together; behind this was a second piece, and behind this again, well crowded back into the pharynx, was a third piece rolled firmly into a wad or ball, of the size of an olive. The removal of this last obstruction enabled the child to breathe well.

Josephine sat in the kitchen all day holding her child wrapped in a shawl, as a substitute for the baby-clothing which she had neglected to provide in anticipation of her maternal duties. In the evening she went to an attic chamber and lay on a lounge with the child by her side. In the same room were two other persons, neither of whom was awakened during the night. About daylight Josephine roused one of her room-mates and said "My baby is dead!" She declared that she suckled the child at about two o'clock, and that then they both fell asleep, the baby lying on her arm. She knew nothing further until she awoke at daybreak and found the child dead beside her. There was no covering, she averred, over the baby's head, and she was wholly ignorant (or assumed to be) of the time and manner of the death.

The autopsy of the child's body (omitting unessential details), disclosed the following conditions: The weight was four and three-quarters pounds, and the length was eighteen and three-quarters inches. The

hair, nails, and centre of ossification in the lower femoral epiphysis indicated mature fetal development. There was moderate lividity of the general surface of the body, and especially of the nails, but none about the lips. The tongue was in its normal position within the mouth. Thick, whitish frothy bubbles appeared at the nostrils. The knees were flexed strongly. There was a diffused faintly-outlined dark blue discoloration of the scalp just above the hair-line of the forehead, but without swelling or other lesion of the skin. The front of the neck, over the hyoid bone, was reddened uniformly, without excoriation or swelling, and the skin above and below this point was more livid than that of the surrounding parts. Dissection of the neck found the appearances normal, except that there was a small ecchymosis at the inner edge of the belly of the right sterno-mastoid muscle; and in front of the angle of the jaw, in the right submaxillary region, there was another ecchymosis of about the size of a grain of rye. The larynx, trachea and bronchi were of normal color internally; they containing a few frothy bubbles. The epiglottis was erect. The upper part of the œsophagus was reddened. The heart displayed a right auricle fully distended with blood. The external vessels of the heart were injected. There were three small sub-pericardial ecchymoses in the interventricular groove. The blood was very dark in color but was loosely clotted. The lungs were quite fully expanded. Their color externally was a light red, with some limited areas of dark red at the posterior surface near the base. There were a few, not exceeding half-a-dozen, punctate sub-pleural ecchymoses along the lower border of the right upper lobe. Sections of the lungs showed a uniform dark red color, with fully developed hyperæmia. The stomach contained a tablespoonful of clear, tenacious mucus, and a small mass of loosely coagulated milk. The spleen, kidneys and liver were injected. The intestines were normal, the colon containing meconium. The dissection of the head disclosed an ecchymosis in the frontal region beneath the discoloration noticed externally. Both frontal bones were fissured from their middle point outward immediately under these ecchymoses. In the occipital region, at the middle point, there was another ecchymosis, without any fracture. The brain was very soft. The meninges were only moderately injected, but the frontal lobes, the right especially, presented many minute reddish points of hæmorrhage within their substance.

Here, again, as in the previous case, the judicial department of the State took a short-lived interest, and the grand jury in due time deliberated concerning the probable guilt of the unwedded mother. The conclusion was that her guilt was not sufficiently manifest to justify an indictment against her. Meanwhile, she had left the country, her errand in Boston having been successfully accomplished.

These two cases satisfactorily illustrate the usual features of such affairs, the characteristics of which are concealed pregnancy out of wedlock, attempted concealment of parturition, neglect to prepare for that event, secret endurance of labor-pains, attempted or accomplished destruction of the new-born child, extraordinary fortitude in the assumption of false appearances during the primary stages of the puerperal condition, and, finally, successful escape from judicial

prosecution. It is unnecessary to multiply examples of this class. I add a brief mention of two cases which will further show the marvellous endurance exhibited by women when urged on by the desire and purpose to keep their obstetric condition a secret. They will also demonstrate some of the difficulties which attend investigations of this character.

CASE III. Mary McC., unmarried, twenty years old, became pregnant for the first time in the spring of 1885. She kept at her work as a house-servant until well into the ninth month, when her increasing clumsiness required that she should have occasional assistance about her duties. Her employer, a widower with a family of young children, suspected her, but did not accuse her. At length, on the morning of November 4, 1885, Mr. B. had to get his own breakfast, his cook informing him through the closed door of her bedroom that she was sick, but would be quite well in a little while. When Mr. B. came home to dinner he found Mary sitting in the kitchen looking so pale and ill that he called a physician, to whom the girl insisted that nothing ailed her save a bad flowing turn after many months' suspension of her menstruation. She denied persistently both pregnancy and parturition, though confronted with the blood-saturated bed-clothing which her chamber offered as proof. The doctor dispatched her to the hospital in spite of her protestations, and after her departure a prolonged search was rewarded by finding the body of a newborn child in the attic of the house, secreted under a pile of rags and blood-stained quilts. The placenta was with it, and the funis was entire.

The child was maturely developed, a well-formed female foetus, weighing nearly eight pounds. The surface of the body was very livid; the lips and tongue were purple.

On the front of the neck, near the middle point, there was a crescentic abrasion, the outline representing very nearly the curve of a finger-nail at the end. Over the thyroid gland, there was a scarcely discernible spot of reddening of the size of a large pea. The scalp was without the caput succedaneum of a prolonged labor.

Dissection of the neck found a very small and distinct ecchymosis on the thyro-hyoid muscle.

The lungs responded negatively to the hydrostatic test; when they were placed in water, either entire or in larger or smaller sections, they sank quickly to the bottom of the vessel. No bubbles appeared when section of the lung tissue was made under water. The organs were of dark color, of dense consistency, with sharp edges, and devoid of crepitation; on their inferior and posterior surfaces were some sub-pleural ecchymoses of the size of a large pea.

The heart was empty and firmly contracted. The stomach and small intestines were empty, their walls being in close apposition. The vessels of the peritoneum were injected as were also those of the meninges. The scalp and skull, however, displayed nothing abnormal.

This case might well be classed as an example of what the books call "infanticide by omission," the mother having neglected to prepare for the birth of her child and having accomplished her desire that the fruit of her illicit pregnancy should perish, not, perhaps, through any overt act of violence on her part, but by her consenting to its death before it lived and breathed outside her body; or while it lay under the

bed-clothing between her thighs, unable to establish the act of respiration.

When informed of the discovery of her child's body the young woman in this case abandoned the false explanation which she had previously given of her extraordinary hemorrhage, and admitted that she had been betrayed by her lover under a promise of marriage, but she had not realized or admitted that her altered form and absent menstruation were the result of that betrayal. She said that at about half-past two o'clock in the morning before her baby was born, she was taken with cramps which awakened her from sleep; these grew more severe until, at half-past four, "the whole thing came away from her at once." She did not hear any cry or feel any motion on the part of the child; she did not lay her hands on it either to harm it or to help it in its birth. She lay quietly in bed till eleven o'clock, flowing freely most of the time; then she got up, dressed herself and carried the dead child to the attic. In the interval between half-past four and eleven, the child lay in bed between and under her thighs where it was born.

The only anatomical disproof of her statement which the autopsy developed was the extremely slight echymosis on the front of the neck; but this was outweighed by the many negative indications that the child had died as a fetus before it had lived as a person.

CASE IV. Annie P., a cook in a gentleman's family occupying a suite in a well-known apartment hotel near Commonwealth avenue was suspected, not of any unlawful act involving the reproductive organs, but of the larceny of sundry articles of value belonging to her employers. This suspicion having ripened to full maturity, detectives were called in to interview her. Their examination of her was long and thorough. Their conclusion was that the girl was probably guilty and they so reported to the family. The head of the household, after consultation with the officers, decided to discharge her from service at once, rather than to proceed against her on a criminal charge, and she left the hotel late in the evening to go to her home in another part of the city. As she left, she asked and received permission to return early the next morning to take away "a bundle." Just after she had gone, and while the officers were still in the building, the chambermaid went to the wood-bin of the suite below to see if "Annie had secreted any of the stolen things there." She found a bundle, but not the one she sought; the bundle contained the body of a new-born child. Near it were sundry articles of feminine underwear much soiled with blood. In the hopper of the adjacent water-closet, a blood-stained night-gown was found by the officers. No placenta was discovered. It was agreed that it would be best to await the girl's appearance in the morning, upon the ground that this proof of her anxiety about the "bundle" would be of value in case of need. True to her appointment, she appeared early the next day, walking towards the hotel where she was presently taken into custody by the officers to await the result of the autopsy of the child's body. The medical examination developed the fact that the child was still-born; or to state the matter more accurately, that evidence of living birth was wholly wanting. The mother was thereupon permitted to continue her puerperal convalescence in the City Hospital, under the care of Dr. Doe, whose first procedure in the case was to remove a full-sized placenta

from the patient's vagina, where she had carried it more than twenty-four hours. Her story of the child's birth, when all motives of secrecy were removed, was as follows: She admitted the illegitimacy of her offspring and estimated that she was about three weeks before her full term when the birth occurred. She made a misstep in her kitchen in the afternoon and this mishap was followed by a few slight cramp-like pains. She went to bed, however, as usual, and slept till she was awakened at about half-past two o'clock in the morning by regularly recurring pains. She got up at three and lay on the kitchen floor. After two hard pains, the child came from her. She made no outcry. There was so little disturbance that the girl who occupied with her the bedroom immediately adjacent, was not awakened, though the door was open. When the child was born, she fell into a swoon or stupor, and lay quietly on the floor for about ten minutes. Then rousing herself, she found her baby lying dead between her thighs. She reached up to the kitchen table, found a pair of scissors there and cut the navel-cord close to her own body. As soon as she felt able, she washed the blood from the floor, wrapped the child's body in her skirts and placed it in the wood-bin behind the kitchen. In the afternoon, she carried it to the place where it was found, meaning to take it away and dispose of it at her earliest opportunity. During the day, she attended to all her duties, preparing the three meals of the family as usual, and fancying, until she fell into the hands of the officers, that her secret was safe. She made a good recovery, without any accidents or complications.

(To be continued.)

DETACHMENT OF THE RETINA IN BOTH EYES WITH ALBUMINURIA OF PREGNANCY: REPLACEMENT OF RETINA.¹

BY O. F. WADSWORTH, M.D., BOSTON.

DETACHMENT of the retina is so infrequent in connection with the albuminuria of pregnancy, that I wish to place a case on record. The case is further interesting as presenting what is also quite unusual in albuminuric retinitis, very extensive choroidal changes.

Mrs. —, twenty-seven years of age, was of rather delicate constitution, but generally in good health. She had a light attack of scarlet fever in the winter of 1885, which confined her to bed only two days, and for six months following the attack had occasional back-ache. She was married in the winter of 1886, and when I was called to her early in March, 1887, was about seven and a half months pregnant.

Except that for a short time she thought she was growing stout, probably due to a little oedema, no unusual symptom was noticed till February 23d, 1887. On that day oedema of the eyelids was observed, but excited no particular attention.

February 27th, she took a walk out of doors and got rather tired, and on the morning of the 28th complained of indistinctness of sight. As this continued and increased, Dr. C. P. Putnam was summoned on March 2d. There was then moderate oedema of eyelids and legs; quite poor vision; the urine was loaded with albumen, and contained many hyaline and granular casts.

March 3d, I saw her in consultation. There was

¹ Read before the American Ophthalmological Society.

moderate edema of the eyelids. The media were clear. There was slight haziness of the disc and all the posterior part of the retina in both eyes; the retinal veins were perhaps a little larger and darker than natural, but there was no marked change in the vessels, which were everywhere clearly seen. In the right eye there was a very general detachment of the retina, mostly with but a thin layer of fluid between it and the choroid; but well toward the equator outward the retina curved sharply forward and its vessels appeared quite dark. At the macular region the refraction was some 5 D. less than at the disc; the retina here was not quite transparent, and showed, when accurately focussed, very faint parallel grayish lines; at the centre was a redder oval, not so red, however, as in the normal condition. In the left eye also was a detachment of the retina of considerable extent over the posterior part of the fundus, but of less degree than in the right. The appearances in the macular region were similar to those in the right. No attempt was made to measure the vision.

March 4th, pilocarpine nitrate, gr. $\frac{1}{2}$, was injected subcutaneously. This caused much sweating and salivation and some vomiting, and, as the directions given were misunderstood, Mrs. — continued sitting up in bed for a long time and became much exhausted. The following night she had a good deal of headache. During the next two days she thought her sight better.

March 6th, the haze of the discs and the surrounding retina was somewhat greater, but the retina in and about the macular region was decidedly less prominent; indeed, in the left eye no detachment in this region could now be made out with certainty. Toward the equator in the right eye there was a prominent detachment along the outer and lower parts—in the left, prominent detachment along the inner and lower parts. In the upper and inner equatorial region of the right eye, the upper and outer of the left eye, the retina was in place and of normal appearance. There were one or two small hemorrhages in each retina. On hasty examination of the vision, words about equal to 2.25 Sn. were read.

March 7th, subcutaneous injection of pilocarpine was repeated.

March 8th, still more haziness of discs and retinae, of faintly yellowish tint, but not enough to obscure the vessels materially. The central portion of the retina perhaps less prominent in the right eye, the grayish markings on this part (resembling the lines on a coarse lithograph) rather more distinct. The bulging detachment toward the equator was now wholly below the horizontal meridian in each eye. Right, words of Sn. 3. Left, words of Sn. 1.5.

March 9th, there was great edema of one labium, to relieve which the patient lay flat on her back, and headache, which had generally been present in some degree since the 4th, was much more severe on the 10th and the following night, and vision became worse.

The morning of the 11th, the opacity of the retina had increased in both eyes, and in the left eye there was a faint appearance of radiating stripes around the macula. In the right eye it was doubtful if there was actual detachment in the macular region, and that in the lower equatorial region was less, but over a small space a little downward and inward from the disc the retina curved forward. In the left eye no detachment

could be made out anywhere. Vision was decidedly less, but as it was thought this might be the effect of the headache, which still persisted, although not severe, it was tested again some hours later when the headache had passed off, and was then in each eye much as on the 6th.

The night of the 11th, headache was again very severe. 2 P.M. of the 12th, examination with the reversed image only, while the patient was lying down, gave about the same condition as on the 11th.

Meanwhile the urine had ranged from 40 to 503 in the twenty-four hours, except once, during which time pilocarpine was given, when it was 273, and the bowels had been kept free. It contained one quarter to one half per cent. of albumen, broad and narrow hyaline, coarse and fine granular casts.

The afternoon of the 14th, consultation with Drs. Minot and Chadwick. There was now found a considerable amount of ascites, which had not been present twenty-four hours before. It was decided to induce premature labor. During the consultation slight pains had begun, and these were encouraged. About midnight there was a sudden convulsion. Ether was given, she was bled about 163, and delivered at 4 A.M. of the 15th. The child was got to breathe after considerable manipulation, and did well.

The mother convalesced slowly but uninterruptedly. Vision was at first very low; sixty hours after delivery she could see only movements of the hand in a shaded room.

March 26th. Vision had improved during the last few days so that she could see that her baby was wrapped in a plaid blanket. In each eye the disc outline was indistinguishable, the whole posterior part of the retina gray, opaque, sprinkled with whitish soft-edged patches and small hemorrhages; in the left were radiating stripes around the macula, somewhat more pronounced than on the 11th. No detachment could be made out in the left eye, but in the right, far downward, the retina bulged forward over a small area, on which the vessels appeared very dark. In both eyes, well upward and laterally, the retina was transparent, and there were seen irregular pigment changes in the choroid, partly lighter, partly darker than normal.

April 14th, she saw, as she had for some time, "as through a moving veil, as of falling water," but much better. She read slowly at 10" words about equal to Sn. 1.75. The eyes were not tested separately, but the left was evidently the better. L. F. of normal size. R. F. a little contracted above, in other directions normal. Right, disc outline rather indistinct; a few white spots about the macula, but the retina generally transparent; numerous and extensive changes in the epithelial and choroidal pigment, darkish patches extending across the macular region and smaller ones scattered widely over the fundus, also much absorption of pigment; far downward detachment of retina to small extent. Left, the appearance of the fundus was very similar to that in the right, but the choroidal changes, although numerous and extensive, were not so great, and there was no detachment.

Mrs. — was last seen on May 7th, soon after which date she went to the sea-shore. The discs were somewhat more defined, but in other respects the fundus was much the same as on April 14th, except that now no detachment could be discovered in either eye. R., J. 13 at 6" — 8"; L., J. 5 at 6" — 8".

I have been informed that a slow improvement of sight has continued.

NOTE. December, 1887. There is still slight but constant shimmering before the right eye. R. V., with $(-)$ 36, $\frac{1}{2}$. There are small defects in the central portion of the field, but the extent of the field is normal. L. V., with $-20 - 21$ cyl. axis 20° , $\frac{1}{2}$; field normal. The pigment changes in the fundus are somewhat less, and the white spots in the macular region have disappeared. The retina is everywhere in place.

Clinical Memorandum.

HYDRAMNIOS.¹

BY WILLIAM INGALLS, M.D.

Mrs. S., twenty-seven, in labor with her second child, June 15, 1887. My first examination proved the os to be high, patulous, admitting the finger, which touched, I thought, the head of the child, which was stationary during a pain or two, and that the vagina was roomy. Two hours later the pains had become stronger, the os somewhat dilated and still high, and the membrane in contact with the head. I now examined the abdomen which was large, not "globular" in form, undulating during pains as well as in their intervals. At the end of another hour pains had become stronger, the os a little more dilated and not much lower, the membrane still tightly covering the head. I now tore the membrane but not an ounce of fluid followed. Forceps were applied and the delivery was followed by a torrent of amniotic fluid for four or five seconds. The child was perfect.

In November, 1885, Mrs. S. was delivered by instruments of her first child, which was born dead.

In June, 1886, she was attended by Dr. Buckingham, who reports from the patient that "her menstruation began one month after the birth of her first child, and has appeared with intervals of six or eight weeks ever since, that for the last eight weeks she has been flowing constantly. Her opinion is that she has had a number of abortions and that she now believes herself pregnant, and that she has felt motion; has had no morning sickness." Dr. Buckingham continues; "abdominal examination proves little or no enlargement; vaginal, proves the os to be wide-mouthed, the cervix torn; absence of fœtus, no clots nor pains."

Persisting in the belief that she was pregnant, Dr. W. L. Richardson was called in consultation, who assured her she was not so. Treatment was advised but declined, on account of her unshaken opinion. Counting back, conception took place about three months after the visit of these gentlemen.

In the "selected obstetrical works of Sir James Y. Simpson," there are these items:

"*Hydramnios*, large size and globular form of the uterus, with no irregularities; tenseness of the abdominal parietes; absence of fetal movements; rapid increase of the size of the abdomen; pain in different parts of the uterus, especially in the groins and pelvis; œdema or anasarca of the lower extremities; difficult respiration; on examining 'per vaginam,' the inferior surface of the uterus much expanded; ballottement unusually free and distinct. Treatment, rupture the membranes."

In my case there was not globular form of uterus, nor was there irregularity. There was no tenseness of abdominal parietes even during pains; no œdema or anasarca of lower extremities. The lower segment of the uterus was expanded.

The subject "*Hydramnios*" is treated quite fully in Charpentier's *Encyclopædia*, there being reports from forty-five observers: plural births, deformity of fœtus, thickening of membranes, fœtal ascites, faults in the cord, and other mal conditions; the observation by the author after their recital is this: "We, therefore, conclude that pathological anatomy gives us no certain data; for all the above lesions have often been found in cases in which there was not the least trace of dropsy of the amnion." In the only case under the writer's care, which occurred years ago, the child had double hare-lip and fissure of palate.

McClintock noted that out of thirty-three cases of hydramnios, one terminated in abortion at five months, one at six months, ten in premature delivery; in twenty-one cases the child appeared to have obtained the normal term, nine of them still-born, five of them putrid, ten born alive but died in a few hours after birth.

It is between the fifth and seventh month of pregnancy that the realization of some abnormality is manifested by those who do not go on without mishap.

Reports of Societies.

PROCEEDINGS OF THE OBSTETRICAL SOCIETY OF BOSTON.

C. M. GREEN, M.D., SECRETARY.

NOVEMBER 12, 1887, the President, DR. WILLIAM L. RICHARDSON, in the chair.

DR. DRAPEL read a paper on

SOME OF THE OBSTETRIC AND LEGAL RELATIONS OF INFANTICIDE.¹

DR. BLAKE said that the present laws concerning infanticide were defective, and he believed it to be the duty of medical men to strive to effect such a change in the laws that guilty mothers can be punished. The cases reported by the reader illustrated what he believed to be the fact that there is less danger in labor among the classes least removed from a purely animal creation,—apparently on account of the comparatively low development of the nervous system. In the highly civilized classes conditions and results vary widely from those observed in women of a low grade of civilization.

DR. J. P. REYNOLDS said it was an interesting inquiry whether the state of the law is responsible for the present careless view of fetal life, or *vice versa*. It is a remarkable fact that many people do not think that the fœtus has any rights in the first half of pregnancy; and it is astonishing to see how many married people think it is no crime to destroy fetal life. He questioned whether it was a well-established fact that women delivered in the manner described by the reader did well without good subsequent care: he believed that without careful after-treatment such women often had trouble. The reader's cases had good care in a hospital.

¹ Read before the Obstetrical Society of Boston, November 12, 1887.

¹ See page 7 of this number of the Journal.

DR. SINCLAIR said that in regard to the criminality of abortion the moral sense of very many people was blunted; he had been generally unsuccessful in his efforts to persuade people against resorting to this unnatural escape from their trouble.

DR. STRONG asked the reader what the legal distinction was between the abortionist and the mother who killed her new-born infant.

DR. DRAPER replied that abortion was considered by Statute law as a crime against the mother and not against the fetus. He thought the present law was wrong and should be changed so as to designate the work of the abortionist as a crime against the fetus.

The PRESIDENT asked the reader whether, in case a child's head only is born and the child breathes, it is considered alive enough to inherit property, but not alive enough to be killed.

DR. DRAPER said such was the fact. He would like to have an expression of opinion on the following hypothetical cases:

1. A primipara is accused of infanticide, her new-born baby having been found dead in a privy-vault; the plea in defence is precipitate labor, and that the baby was born and fell into the vault while the mother was in the act of defecation. Is this plea a good one?

2. A new-born infant is found dead with fracture of the skull; the mother's plea in defence is that she being in precipitate labor the baby was suddenly expelled and fell upon the floor, and that she could not help it. Is this a valid plea?

DR. J. P. REYNOLDS said he was once called to a primipara in labor and found her sitting on a chamber-vessel, and in the vessel was the baby, drowned in the liquor amnii: the child was a large one. There was no evidence that the mother was responsible for the accident, although it is hard to imagine how the mother could have mistaken the expulsion of a large fetus for the passage of feces.

DR. BUCKINGHAM, a guest, spoke of a patient at full term who had had a slight sensation of discomfort only; but when she arose from a seat at the window to go to her bed, the baby was delivered on the floor.

DR. BOARDMAN had seen two instances of precipitate labor in the same patient. In one instance, as the mother was stooping over a chamber-vessel, the baby was expelled and struck the vessel, without, however, suffering injury. In a subsequent labor, the woman was delivered suddenly while standing; but the baby was saved from possible harm by being caught before it struck the floor.

The PRESIDENT spoke of a girl of about eighteen who was sent into the Rotunda Hospital in Dublin, having had slight pains in her stomach: she was found not to be in labor. In the evening, while the girl was waiting, the baby was born suddenly without, according to her own statement, any pain.

As an illustration of the apparent impunity with which women often resume their daily affairs soon after labor, DR. FARLOW, a guest, cited the case of a washerwoman who went to her employer's and performed her usual day's work, and returned for the same service a week later. In the intervening week she had given birth to twins of full size.

DR. DOE once attended a primipara in severe labor followed by hæmorrhage: on the third day thereafter she was found at the wash-tub.

DR. ABBOT mentioned the case of a iv-para whom he delivered of twins, and who got up the next day

and resumed her work: she never had any bad symptoms. In another case, to which he was once called before breakfast, the baby was born before his arrival and the mother was found sitting up washing her breakfast dishes.

DR. FORSTER cited the case of an unmarried girl, who was delivered unattended, who cut and tied the funis herself, carried her baby to an asylum and then walked to the Hospital: she made an excellent convalescence.

As an instance of the occasionally observed ability of women to bear the pains of labor in silence in order to conceal their condition, DR. GREEN mentioned the case of a primiparous girl of seventeen, who, being in a lodging-house, did not wish the fact of her being in labor to be known in the house. The labor was twelve hours in duration and was terminated with forceps, and no anæsthetic was used. Throughout the labor and the forceps delivery no sound escaped the patient's lips: she made a speedy and non-febrile recovery.

DR. RICHARDSON cited the case of a cook who served dinner for a dinner-party and remained at her post until the meats were sent up. She then went upstairs, was delivered of a living child, tied the cord, and returned to the kitchen in time to serve coffee and dessert: she then fainted and fell to the floor.

DR. INGALLS read a brief paper on

HYDRAMNIOS.²

DR. FORSTER reported the following case of

INVERSION OF THE UTERUS.

"Inversion of the uterus is a rare occurrence. Braun states that of 150,000 births in the clinics respectively under the charge of Spæth and himself, not a single case of complete inversion has come to their notice. There was one case in 190,000 confinements at the Rotunda Hospital in Dublin."

Reading this in Lusk, after returning from a confinement case early last Monday morning, I thought the following case would be of sufficient interest to briefly report:

Sunday afternoon I was called to Mrs. S., twenty-seven, American, in labor with her first child. At about 5 p. m. the membranes broke, and a breech and right foot presented. The pains were regular, and the patient's strength good. After the scrotum appeared at the vulva slow progress was made, and at 12 p. m. I decided to give ether and deliver. Ether was given at quarter of one. The administration of the anæsthetic was intrusted to a brother practitioner, whose assistance I had obtained for that purpose. The delivery was easily and rapidly made by first bringing down the presenting foot, there being no compression of the cord. The child was alive, and soon cried lustily at five minutes of one. The delivery of the head caused a tear of the perineum, necessitating the introduction of two stitches. My assistant offered to take charge of the placenta while I prepared my needles. This I allowed him to do; returning to introduce the suture, I was surprised to find what I first thought to be the placenta occupying the vagina, but he quickly informed me the placenta had all come away, and I then remembered seeing it in the basin. Sooner than it takes to write it, I was horrified to see the uterus completely inverted and

² See page 13 of this number of the Journal.

outside the vulva. I lost no time in returning the organ, and with comparative ease succeeded, although at first it required considerable force. Some hæmorrhage followed, but I carried up some ice and was soon able to check it, the uterus rapidly and firmly contracting. The rent in the perineum was stitched, and by two o'clock, the pulse being at 78, I left the patient.

Antisepsis, as practised at the Boston Lying-in Hospital, was used throughout the case, with the single exception that the ice was taken from a basin of water caused by the melting of the supply provided for such an emergency as occurred.

There was no symptom of shock present, and really very little hæmorrhage. On the third day two odorless clots came away, and a large one on the fourth. The lochia had been inoffensive, the uterus firmly contracted, the milk-supply sufficient, the patient comfortable.

THE NEW YORK ACADEMY OF MEDICINE.

STATED Meeting, December 15, 1887. DR. T. H. BURCHARD read a paper on

THE MODERN TREATMENT IN STRANGULATED HERNIA.

He said that, encouraged by the remarkable successes obtained in the treatment of non-strangulated hernia by the methods suggested by Banks, Czerny and others, surgeons had lately paid special attention to the radical cure operation as applied to cases in which strangulation existed, and the results achieved had been most gratifying. The general principles upon which, as a legitimate surgical procedure, the operation was based were the following:

(1) A more general recognition by the profession of the value of time in the earlier stages of the strangulation; so that surgical relief could now generally be rendered before pathological changes which were irremediable, had taken place in the tissues.

(2) Modern herniotomy implied an abandonment of those uncertain and pernicious methods and practices which, founded on a false pathology, had sought to relieve the strangulation by producing a condition of systemic relaxation. It was now recognized that spasm, as a causative agent in the production of strangulation never exists.

(3) Modern herniotomy restricted the employment of taxis to within limits which were rational and safe. Necessary as properly directed taxis was in the reduction of strangulated hernia, by its indiscriminate and reckless use irreparable damages had not infrequently been done the intestine; and he could not but feel that it had been a misfortune to designate by a special appellation the manipulations employed in reducing hernia, since the practice had exaggerated their importance in the treatment, and been a fruitful source of abuse.

(4) Modern herniotomy implied the early resort to a cutting operation. Many lives had had to be sacrificed before the profession seemed to realize that the gangrene and ulceration, the fecal extravasation and stercoraceous vomiting, the peritonitis and collapse, were not necessary and integral portions of the primary conditions of strangulation, but secondary complications, developing later on in the progress of the disease, and the legitimate result of delay in affording relief to the original constriction. If, however, the strangulation

were relieved before inflammation of the gut or adjacent tissues had supervened, these grave dangers could be avoided. The practice advised by Dr. Burchard was, if possible, to cut every case of strangulated hernia in which gently applied taxis, under anaesthesia, preceded, as a rule, by the application of ice, does not yield reasonable expectations of success within about one hour after positive symptoms of strangulation have presented themselves. In his opinion nothing was gained by delay, while everything was risked.

(5) Modern herniotomy was an antiseptic operation; demanding the fullest application of Listerian principles.

(6) Modern herniotomy required in the disposition of the hernial sac the finest impartiality of judgment. Certain cases required incision, while in others the strangulation could be readily reduced without opening the sac; so that it would be folly to thus complicate the operation and expose the patient to unnecessary danger.

(7) Since Mitchell Banks, of Liverpool, had urged the possibility and expediency of perfecting the old operation of kelotomy, so as to add to the operation done for the relief of strangulation the inestimable advantages of an operation for radical cure, the strongest possible encouragement had been given for the attainment of an early, thorough and perfected operation.

Regarding the special treatment of strangulated hernia, Dr. Burchard said that he had nothing novel to add to the excellent recommendations already published on the subject. His experience had led him to the adoption of a plan of treatment substantially as follows:

(1) Pain allayed, vomiting quieted, and nervous tranquility secured by the hypodermic administration of morphia with atropia.

(2) As soon as practicable a careful examination is made of the hernial tumor; any attempt at reduction being studiously avoided.

(3) If evidences of local inflammation are present, or if there is much swelling of the tumor, a poultice of flaxseed meal and cracked ice, or the ice-roll is at once applied; these being dispensed with, however, if the patient is feeble or the strangulation is of long standing.

(4) A stimulating enema of turpentine and oil, or a large emollient of thin flaxseed tea, is administered, and the rectum thoroughly washed out. Should it be required, the patient is catheterized. If the tumor is at all disturbed no attempt at taxis is made until

(5) The patient is anaesthetized; permission having first been obtained to proceed with the operation in case taxis should fail.

At this point, Dr. Burchard said he wished to emphasize the advantages to be gained by putting the patient under full anaesthesia (preferably by chloroform), covering the tumor with a rather large and heavy ice-poultice, elevating the lower extremities, and keeping the hands entirely off for a period of from thirty to forty minutes. In a number of instances thus treated he had had the satisfaction of seeing the tumor almost imperceptibly slip back of itself, even after prolonged taxis had been unsuccessfully employed. As to just how long the attempt at reduction by taxis was justifiable, no absolute rule could be laid down. To the practised touch a moment was sometimes sufficient to determine the possibility of a suc-

cessful reduction. In other cases it was advisable that the trial should be prolonged for twenty, or even thirty, minutes, provided always that only the gentlest manipulations were employed.

Taxis having proved unsuccessful, the operation should at once be undertaken. By careful dissection the sac should be fully exposed; when, if the strangulation were of recent occurrence, and the sac free from inflammation and of normal appearance, an effort might be made, by gentle taxis, to secure its return into the abdominal cavity. Should adhesions bind down the sac, they might be broken up if not too extensive; precautions being taken that all bleeding has been effectually checked before the sac is returned. If constricting bands should girdle the body of the sac and prevent its return, they should, if possible, be divided. Adhesions around the neck of the sac were to be treated with great deliberation. Having pointed out the complications and dangers to which such adhesions might give rise, he mentioned that serous effusion within the sac might be safely gotten rid of by puncturing the sac with a capillary hypodermic needle.

If now the sac could not be readily reduced, he went on to say, it should be carefully opened. Unprejudiced surgeons, he thought, were at present agreed that in all those cases where it would be safe to replace the hernia by simple taxis, if that were possible, the same might be done after restraining adhesions of the sac or constricting bands around its neck had been dividing with the knife. But in those cases in which the symptoms were suggestive of an aggravated condition of the bowel, and on account of which it would be dangerous to attempt to reduce it by taxis, it was necessary to open the sac. The sac having been opened, the stricture should be sought for and divided.

Dr. Burchard here alluded to some points of practical interest in connection with the return of the gut. One of them was in regard to cases of deep congestion. How far the vitality of the bowel was consistent with change of color, drying of the secretions, emphysematous crackling, and fecal odor, was a difficult matter to decide. He had seen two cases in the practice of the late Dr. James R. Wood in which a gut that was actually purple was replaced, and in both instances with the best possible results. In one case of his own, where a deep furrow marked the seat of the stricture, and where the gut itself was of a dark maroon shade, the condition of the intestine did not warrant its reposition for nearly three hours after the operation: while in another case, of more prolonged strangulation, with grave constitutional symptoms (the condition of the gut being almost identical, with the exception of the furrow, or groove), the circulation was restored in one-fourth the time. He said that he could not feel that we were ever justified in returning strangulated intestine until it gave some evidence of reanimation; while it was perfectly possible to keep it enveloped in moist flannels and rubber tissue for several hours. In cases of ulceration it was sometimes advisable to practice partial excision before returning the intestine, and in some instances the condition did not warrant this until several hours after the operation. Extensive perforations and lacerations occurring in herniated bowel necessitated the formation of an artificial anus.

Treatment of adhesions. If acute and simply binding down the body of the sac, they might be gently

broken down. If they surrounded the neck of the sac, binding the intestine to the upper end of the sac, or the intestine to the cord, or to an undescended testis, it was necessary to accomplish the operation with the greatest possible gentleness and circumspection, on account of the extreme friability of the tissues. Chronic adhesions might be divided with more boldness, provided no traction were made on the inflamed intestine. In all cases the intestine, both above and below the strictured portion, should be carefully examined after the operation.

The radical cure. The modern operation found its greatest advantage in the radical cure it secured by the complete closure of the sac, and the permanent obliteration of the hernial canal; and it had been successfully performed upon all forms of hernia, inguinal, femoral and umbilical, with equally satisfactory results. In the present light of hernial surgery he thought that no operation for strangulated hernia could be said to be properly performed without the final closure of the hernial canal. By this practice five decided advantages were gained.

(1) Complete isolation of the peritoneal cavity, and its permanent closure.

(2) Permanent closure of the patulous orifice through which the gut escaped.

(3) Shortening of an abnormally elongated hernial canal.

(4) Prevention of septic percolation into the cavity of the abdomen in case suppurative should ensue.

(5) The inestimable advantages that would result to the patient from a permanent cure.

In the performance of the operation the clinical requirements were, first, a safe and satisfactory disposition of the sac, and second, the total obliteration of the hernial rings, and the accurate coaptation of the sides of the canal.

Disposal of the sac. The sac might be dealt with in one of several ways:

(1) It may be reduced within the abdominal cavity, and the canal then obliterated.

(2) It may be left within the canal (especially when firm adhesions prevent its safe return), and the superficial tissues and the skin be firmly approximated over it.

(3) It may be ligatured, the hernial investment amputated, and the stump returned.

(4) It may be ligatured and amputated, and then invaginated in the canal.

(5) It may be drawn up upon itself and fixed as a bulwark against the internal ring, as in Macewen's operation.

The abdominal wall may be divided longitudinally and parallel to the pillars, and the sac then woven into the fibrous structure, as suggested by Dr. Joseph D. Bryant.

The first method, he thought, should be dismissed from consideration except in very acute hernia, on account of the danger of causing adhesions, with their attendant pain and discomfort, or of lighting up a peritonitis.

The objection to the second method was that with the sac remaining *in situ* complete obliteration of the canal could not be secured. A canal thus treated became exceedingly sensitive, and a truss could scarcely be worn. Between the remaining methods a choice could sometimes be made only after mature deliberation.

Dr. Burchard said he had operated in nine cases of strangulated hernia, in which he had been enabled to carry out the operation in all its details. Eight of these had recovered, and one died on the fourth day from delirium tremens. Having alluded to a number of interesting points in connection with these cases, he spoke, in conclusion, of two practical matters of importance: (1) In cases of stercoraceous vomiting and collapse, nothing had equalled in his experience the use of hot water employed as a stomach douche, as practised by Tait. A long, soft rubber tube was passed into the stomach, and a stream of hot water very gently injected in a continuous current. By this means the stomach was not only thoroughly washed of its fecal contents, but the best possible stimulant in cases of hernial collapse was furnished by hot water so employed. (2) As a factor in the production of acute general peritonitis, concealed hernias in exceptional localities were apt to be overlooked. He had met with two instances of this kind in his own experience; one being a case of bubonocoele of a direct variety, and the other one of concealed femoral hernia.

Dr. ROBERT F. WEIR made some remarks on the question,

HOW SHALL THE SAC BE TREATED IN HERNIOTOMY?

He said that Dr. Burchard had covered the ground so completely, that but little remained to be said. Like Dr. Burchard, he thought that the surgeon should be guided by the circumstances of each individual case, and he did not advocate any one method of procedure to the exclusion of others. He illustrated by diagrams the operations for radical cure by Macewen and Czerny, and went on to say that while the radical operation unquestionably marked an improvement in this branch of surgery, it could not as yet be regarded as a perfected operation. Having given some statistics showing the comparative frequency of relapses, he said, in conclusion, that surgeons were everywhere practising the operation, and, he feared, too freely; that is, too freely in non-strangulated hernia.

Dr. W. B. DE GARMO read a paper on

THE CONSERVATIVE TREATMENT OF IRREDUCIBLE AND INCARCERATED HERNIA.

He said, in opening, that his paper did not relate in any sense to strangulated hernia. He would present the histories of a number of cases, which were intended to show that the two opposite opinions concerning operative interference and non-interference were both wrong. He would advocate operation in certain cases which could not be reduced, but he thought it unwise to operate in all cases. The first case which he related was one of irreducible inguinal hernia of ten years' standing. The first day, he devoted one hour to making taxis (by which term he wished to be understood as meaning certain very gentle manipulations, which were quite different from the taxis usually employed), but with apparently very little effect. By the fourth day, however, he succeeded in reducing the hernia by this means. At first, a truss could be worn for only a short time, but the tolerance of it gradually increased. The second case was also of ten years' standing, and the hernial tumor was of the size of a foetal head at full term. The hernia was complicated, as was frequently the case, with a piece of omentum, but it afterwards disappeared under the pressure of the truss. After the

hernia was first reduced, it was impossible for the patient to wear the truss in a standing position for a time.

The third case was characterized with attacks of colic occurring in connection with the hernia. The hernia was gradually reduced by gentle manipulations, after which a truss was worn with comfort, and by the end of a year the patient thought himself cured. As a result of jumping from a carriage, however, the hernia became strangulated. An operation was then performed, and he made a rapid recovery. Dr. De Garmo narrated seven other cases, and said, of the ten, there were seven reductions and two failures, while one case was abandoned on account of the patient having diabetes.

He then went on to speak more particularly of the manner of changing these supposed irreducible hernias into reducible ones. The first thing, he said, was to see that the mass was freely movable in the sac, and then use compression, rather than ordinary taxis. In the second place, the tumor was to be separated from the vicinity of the testicle, if it were situated in the scrotum. In other words, it was to be perseveringly stripped from its lower adhesions and gradually worked upwards, no force whatever being used. The complete separation of the omentum so frequently forming a part of the mass was accomplished before the reduction proper was commenced. In some cases, Dr. De Garmo is in the habit of directing self applied taxis, to be practised daily. After the reduction, the hernial sac usually remained; but if the hernia was kept properly in place by a well-fitting truss, the sac often disappeared in the course of time. Taxis was to be practised from fifteen to forty-five minutes at a time, and repeated once a day. None of his patients had been confined to bed for more than one week.

In those cases in which it was found impossible to reduce the hernia the tumor was compressed by a truss, and a strong suspensory support was also employed. It was important, however, to distinguish the contents of the tumor. If only omentum were present no trouble would result, but if bowel were present the truss would be apt to cause more or less discomfort, and probably lead to strangulation.

Dr. H. G. GERSTER read a paper entitled

REMARKS ON STRANGULATED HERNIA IN CHILDREN.

This, he said, was a very rare condition in children, and he had met with but four instances of it in his experience. There was nothing peculiar in the character of the strangulation in such subjects, and he would direct attention only to a point of difference in the treatment required, as compared with that in adults. This was on account of the difficulty of preventing infection of the external wound in small children. In most instances the hernia was congenital, and the neck of the sac was usually not very wide. On account of the danger of infection he advocated an open treatment of the wound. Primary union did not occur after suturing, and, therefore, after securing occlusion of the sac and the abdominal opening, he packed the open wound with iodoform gauze, and thus secured an aseptic condition.

Dr. Gerster then proceeded to relate the histories of the four cases that he had seen. In one of them, a child two years and three months old, an error of diagnosis was made. The tumor was at first mistaken for hydrocele; but the true nature of the case became ap-

parent when the hypodermic needle was inserted and brought away intestinal matter. It was also found to be a strangulated hernia; but as no urgent symptoms were present no active interference was made at this time. By the next day, however, all the ordinary symptoms of strangulated hernia had manifested themselves, and the radical operation was performed. During this, a slight wound was made in the gut on account of the adhesions present, and this was sewed up with the Lembert suture. In another of the cases, strangulation of the hernia occurred four separate times in connection with eclamptic attacks, to which the child was subject. It was always successfully reduced under the use of chloroform; but when the accident happened the fifth time it was determined to perform the radical operation, after which there was no further trouble from the hernia.

DR. V. P. GIBNEY said that he should like to make some protest against the strong condemnation of taxis which Dr. Burchard had expressed, as he had seen a number of aggravated cases of strangulated hernia reduced under taxis as employed by the average practitioner. As regards strangulated hernia in children, he did not recall a single instance in all his experience in which the strangulation could not be reduced with the aid of chloroform. Furthermore, if it could be reduced, it could be cured simply by the wearing of a suitable truss. As the operation was a more serious one than in adults he thought, therefore, that operative interference should never be resorted to in children; and such interference became still less necessary in the light of the successful results accomplished by the conservative methods advocated by Dr. De Garmo this evening.

DR. WEIR said that he had had two cases in children like Dr. Geyster's, and both had proved fatal. In two other cases he had successfully reduced the hernia without operation, by resorting to the expedient of inserting the finger into the rectum, and thus combining internal with external pressure.

DR. DE GARMO said that he had met with only temporary incarceration in children. No bad results had ever occurred, and he had never found it necessary to resort to taxis in such cases. In reply to a question from Dr. Weir as to just what he meant by taxis, he said that the gradual working of the tumor loose by passing the fingers around it was not taxis proper, but rather pressure. By taxis he meant the manipulation of the neck of the sac, but employed in such a way as to avoid pressure back against the abdominal rings, which was apt to be resorted to in taxis as commonly practiced.

NEW YORK NEUROLOGICAL SOCIETY.

STATED meeting October 5, 1887, the President, C. L. DANA, M.D., in the chair.

CASE OF CONGENITAL ABSENCE OF THE FACULTY OF CO-ORDINATION.

DR. G. M. HAMMOND presented a boy four years of age, brought to his clinic on account of inability to walk. He was born at full term. Labor was natural. He appeared to be perfectly healthy at birth, but shortly afterward he became sick, and continued more or less ill for six months. The attending physician diagnosed colic. Since recovery from this attack

the patient had had no sickness. The special senses were normal. The patient understood as well as other children of his age. Perhaps he did not speak as plainly as he should, but two other children in the family, perfectly healthy, talked in the same manner. There was no history of syphilis. The patient was well formed. The muscles of the limbs were well developed for a child who did not walk. Muscular reaction to both electric currents was normal. The reflexes were normal. The only apparent reason for his inability to walk was want of power to retain his equilibrium. He could crawl on his hands and knees perfectly well unless he attempted to go very fast, when he would fall, and he always fell toward the right. He could stand holding to a chair, and walk pretty well if held upright. There was also inco-ordination of the upper extremities. He widened his base in standing. Dr. Hammond had not decided whether there was congenital absence of sensory tract in the cord or cerebellar disease.

DR. JULIUS RUDISCH had seen two similar cases, both in girls, one about eight years old and the other about thirteen. The first was seen some years ago, was under observation but a short time, and his recollection of the case was indistinct, but he was impressed with what he took to be muscular weakness, not simply ataxia, but weakness in the back. The child, if sustained, could walk well; if not sustained it would fall, like the boy represented by Dr. Hammond. The older patient could walk, but in a peculiar ataxic way in the position of marked lordosis. The legs were well developed, and for that reason he thought the trouble was in the muscles of the back. The cases were not, in his opinion, congenital locomotor ataxia.

DR. N. E. BRILL thought such cases were not uncommon, especially among idiots. The gait of the boy presented reminded him of the swaying motion of a cat sent Dr. Spitzka by Professor Wilder. Other actions than walking were natural. Rumpf reported a similar case and found a rudimentary cerebellum. Dr. Spitzka removed the cerebellum of this cat and found it natural. Dr. Brill thought we had to distinguish in these cases between locomotor ataxia and static ataxia. Dr. Hammond's case appeared to be one of static ataxia due to rudimentary cerebellum.

THE PRESIDENT had found in his case-books one in which a provisional diagnosis of infantile ataxia was recorded. The girl, about two years old, was well-nourished, large. Could not co-ordinate the hands or feet. In addition there were some forced movements: the head would suddenly plunge forward.

VESICO-GENITO-POST-FEMORAL NEURALGIA AND NEURITIS.

DR. LANDON CARTER GRAY read a paper, in which he described two cases, seen during the year, of a peculiar variety of neuralgia and neuritis that had not, so far as he had been able to ascertain, been hitherto described. The first patient was a man aged forty, good general health, but marked lithamic temperament, subject every summer to quasi-malarial attacks. Hitherto his neuralgia had been gastric, or intestinal. He escaped his usual attack this year until in July the temperature fell in one night forty-eight F., and on the second day following, when getting out of bed, the patient felt a sharp tingling pain

through the buttocks, perineum, scrotum, tip of the penis and down the back of both thighs to somewhat above the knee. Some slight smarting was felt in urination. Toward the afternoon the pain began to lessen, but became much worse again, following a Turkish and Russian bath. The cutaneous pains became violent, urination scalding, the bladder became parietic. The urine had to be forced into the urethra. For four days the temperature was from 100 in the morning to 102 or 103 in the afternoon, the neuralgic symptoms still existing.

The second case was that of a female, aged thirty-five, seen in consultation with Dr. Burge, September 6th. During the past two years the patient had had a good deal of sciatica; otherwise had had good health. In December last she was suddenly attacked with sharp pain in the buttocks, perineum, labia, and down the back part of the thighs to the knee. There was simultaneous retention of urine, requiring the catheter. Several weeks later Dr. Burge saw the patient and found tactile anaesthesia of the buttock, perineum, labia, and the back part of the thighs to just above the knee. Dr. Gray saw the patient nine months after the onset of the trouble. She then had vesical anaesthesia, and voided urine without her knowledge. Over the area just mentioned, except the labia, which he was not allowed to examine, he found impairment of the tactile, temperature, and pain senses, but slightly less marked near the knee than above. There had never been any motor impairment.

These cases had a clinical interest because a knowledge that such a neuralgia might occur would make us chary about diagnosing a central affection, as we might well be inclined in the early stage, especially when there was vesical, motor, or sensory paralysis.

Dr. RUDISCH asked whether an examination had been made for prostatitis, which caused symptoms in a degree like those described.

Dr. GRAY said the area of distribution of the pain was not like that in prostatitis; besides, the second case occurred in a female.

Dr. W. H. THOMSON referred to the case of a woman from the country, a locality said by her physician to be free from malaria. After a prolonged convalescence from an attack of pleurisy she began to suffer severe pain in the anterior part of the left thigh, and from slight trouble with the bladder, the pains coming on certain days of the week, lasting one day and two nights. This continued five months, when she was free until the following fall. The medicine prescribed by Dr. Thomson had not prevented a return of the singular symptoms again the present fall. There was no indication of sciatica.

DISCUSSION ON THE USES OF HYOSCYAMINE.

THE PRESIDENT stated that there were two preparations of the drug, the crystalline and the amorphous, the former seemed to be similar in property to the opiates, while the latter seemed to have neurotic properties. He had heard that hyoscyamine was employed in the asylums for the insane in New York, but not very successfully, whereas in the asylums of Pennsylvania its success had been marked. He had employed hyoscyamine in paralysis agitans, in chorea, and in a few cases as a hypnotic, and it had been employed as a hypnotic to a considerable extent in his service at Bellevue Hospital. The number of cases of chorea in which he had used it was six; in three it

was noted to have been of benefit, or caused very rapid or very marked improvement. One of the cases was marked, and had not yielded to other treatment. In three cases the results were very doubtful. He had employed it in four cases of paralysis agitans, in two, he thought with unquestionable benefit. In two it seemed to produce no benefit. On the whole, he thought that unless given at rather an early stage of paralysis agitans it did no good. The form employed in chorea and paralysis agitans was the crystalline, but he was not sure that the amorphous form would not be the better preparation in such cases. He thought we could get along perhaps as well without as with hyoscyamine.

Dr. B. SACHS's experience with hyoscyamine had not been very extensive, but he had employed it in a few cases of paralysis agitans, acute mania, and the insomnia accompanying the neurasthenic condition. He had employed only the crystalline form. In contradiction to what the President said, that it was best to give it in the early stage of paralysis agitans, he remembered one case in which every other therapeutic agent had been tried without success, when hyoscyamine was administered in about one-hundredth of a grain doses twice a day, with the effect of making the patient very much more comfortable, and of diminishing somewhat the annoying movements of the hand. In another chronic case it had been of no benefit. He had obtained no effect from the drug when administered to allay the excitement of acute mania. It had also been disappointing in insomnia accompanying neurasthenia. It seemed to be of more value against insomnia from mental restlessness.

Dr. N. M. LESZYNSKY said that about eight years ago it was quite fashionable to use hyoscyamine in asylum practice, and he had employed it in chronic mania, acute mania and epileptic forms of insanity. First, he used the amorphous, and later, sulphate of hyoscyamine; it was claimed that the latter form was easier absorbed, and produced its effects in smaller doses. The sulphate was also preferred for hypodermic use, in which manner he had employed it in one-sixtieth of a grain doses. To patients with recurring attacks of maniacal symptoms the drug was given a few days before an expected attack and continued until the attack was aborted.

In a state of exhaustion, he would regard hyoscyamine as a dangerous drug to administer, but where there was no objection to its use on that ground he had known it to produce sleep where chloral and morphine had failed. Given to patients subject to epileptiform convulsions before menstruation it seemed to avert the attack. He had given it in small doses in two or three cases of chorea, and thought it produced some benefit.

Dr. L. C. GRAY had been using hyoscyamine ever since it had been introduced to the profession, and he must say that, for certain purposes, there was no drug in the pharmacopoeia that he could not better afford to dispense with. The most convenient form was in tablets, one one-hundredth of a grain. In some people hyoscyamine would produce seemingly serious retention of urine. It might also produce disastrous results if given to persons whose general strength was below par. In an old gentleman, with atheromatous arteries, hypertrophied and feeble heart, one one-hundredth of a grain of hyoscyamine caused a condition of collapse. He knew of one patient suffering from

melancholia, who was sent to Greenwood by hyoseyamine. He had given it in two cases of chorea, one being an exceedingly violent case, the child finally dying in a convulsion. To that patient he could never give a second dose of hyoseyamine, because of the alarming prostration which a first dose would cause. In another case in which the child had to be held in bed, the drug proved an effective means of restraint, but the child was always found prostrated to a marked degree the next day. In paralysis agitans it had been very useful, and came to be with him a routine treatment. He thought the reason why it had been more benefit in his practice, was that he combined with it some stimulant or tonic to prevent its depressing effect. He gave with it good food, one or two grains of quinine a day, sometimes alcoholic stimulants. He had satisfied himself that it was the hyoseyamine in this treatment which had a restraining effect upon the movements in paralysis agitans.

But it was especially in cases of mental trouble that hyoseyamine was of great benefit. In insanity with hallucinatory symptoms, especially in the early stage, before the patient could be taken to an asylum, hyoseyamine would do much toward restraining the patient, and it would seem, aided in cutting short the disease. He was very careful to give no more of the drug than was absolutely necessary, and he combined it with bromide of potassium which increased its effect. He had never seen hypnotic effects from hyoseyamine.

DR. W. H. THOMSON said that his experience with hyoseyamine almost from the beginning, rather prejudiced him against it. One of the first cases in which he employed it, was that of a Judge, troubled with insomnia. The next day he was unable to hold court, had bladder symptoms, etc. He found it useful in asthma, with considerable dilatation of the right side of the heart, without bronchitis, but a congested state of the lungs. He had employed it in facial neuralgia, headaches, and various neurotic conditions, but had nothing definite to say about its effects. One patient with paralysis agitans was benefited by it among many with whom it was a failure.

DR. KELLOGG had used hyoseyamine in cases of mental excitement, but it had not proven the sedative he had supposed it would. But it controlled muscular excitement. He had failed to get any hypnotic effect from it. He had not been favorably impressed with its after-effect in acute mania.

DR. H. S. HINKLEY had found it serviceable in allaying maniacal excitement. Dr. Waitzfeld, of the Pennsylvania Hospital for the insane, had used hyoseyamine of bromide, and spoke very highly of it.

DR. RICHARDS had given five to seven drops of a one per cent. solution in several cases of insomnia without effect.

—A grocer was recently prosecuted at Sheffield, England, says the *Medical Press*, for selling white pepper which the analyst said was not fit for use, because it contained decomposing matter, owing probably to the berry having been steeped in urine sewage. The analyst was re-examined, and stated that one method for rubbing off the black husks in order to make white pepper was steeping them in cow's urine. This was done in India. A nominal fine of five shillings and costs was imposed. Notice of appeal was given.

THE BOSTON Medical and Surgical Journal.

THURSDAY, JANUARY 5, 1888.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States and Canada; \$6.00 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 94 Boylston Street.

All letters containing business communications, or referring to the publication, subscription or advertising department of this journal, should be addressed to the "Manager of the Business Department," Medical and Surgical Journal, 94 Boylston Street.

Remittances should be made by money-order, draft, or registered letter, payable to

CUPPLES AND HURD,
94 BOYLSTON STREET, BOSTON, MASS.

EIGHTEEN EIGHTY-EIGHT.

WITH the taking down of the calendar for 1887, and its replacement by its successor for 1888, it becomes once more the pleasant duty of the JOURNAL to extend to its friends, whether readers or contributors, its cordial new-year wishes for their personal and professional prosperity. To all alike, whether they have been long-time subscribers, and have watched the JOURNAL'S growth through many of its fifty-eight years of life, or whether they are now for the first time numbered among our readers, comes our hearty wish that they may long live to enjoy and profit by the good things which we hope and expect to be able to present to them in this and in coming years.

Thousands of babies are to be born in this year of Grace: thousands of men, women, and children are to suffer, as disease, often preventable, too rarely prevented, continues to march in its well-worn path, and the "old, old fashion" of death is to have its multitude of followers. And so the work of the busy physician is ever ready at his hand, as the generations of men, like the leaves of the forest, pursue each other in unceasing round of change.

Οἱ περ φέλλον γενεή, τοῖσδε, καὶ ἀνδρῶν.

For all in our profession who are bearing the burden and heat of the day, it will be our aim in the coming year, as in the past, to bring what best we can of help to the successful accomplishment of their work, and to this end we invite the coöperation of all who can find the will and the opportunity to cull from out of their own especial experience what may be of advantage to their fellow-laborers.

THE PRESBYTERIAN HOSPITAL AND THE NEW YORK HOSPITAL SATURDAY AND SUNDAY ASSOCIATION.

A GOOD deal of unfavorable comment has been occasioned by the withdrawal of the Presbyterian Hospital from the Hospital Saturday and Sunday As-

sociation, on the ground that at a recent meeting of the Association the constitution was amended by the striking out of that part of it which stated that one of the objects of the Association was the encouragement of specially designated gifts to the institutions represented in it. The institution which has taken the most active part in rendering the movement as far as possible unsectarian has been St. Luke's Hospital, under the auspices of the Protestant Episcopal church, which originated the Hospital Saturday and Sunday collections in this country. It is also a noteworthy fact that at first St. Luke's was the only hospital which received the proceeds of such collections, and that ever since the general Association was formed at the suggestion of the managers of St. Luke's, it has always received by far the largest amount of all the other institutions embraced in the Association, in specially designated contributions. Since this action has been taken by the Presbyterian Hospital a number of letters expressing their deep regret concerning the matter from many prominent Presbyterians, including a number of well-known physicians, have been received by Mr. Miller, President of the Hospital Association. Most of these gentlemen have also signed a formal paper in which a large number of the foremost citizens of all creeds offer their cordial support to the Association in its efforts to make the hospital collection entirely unsectarian, and urge the public in general also to stand by it and contribute generously to its funds.

In order that there may be no misunderstanding about the position of the Association, since many erroneous ideas have been circulated in the community, the President and Treasurer of the Hospital Association have published an authorized statement, a portion of which is as follows: "Owing to a change in the constitution by which the clause was stricken out which committed the Association to the stimulating and fostering of designated gifts, it has been inferred that designated gifts will be no longer received." This is a mistake, and the position of the Association regarding this matter is best stated by quoting a passage from its last appeal, which reads: "Contributions are especially solicited for the general fund, which will be divided among the associated hospitals on the basis of free care for the sick poor. Gifts may be designated, however, for any hospital in the city, and such gifts will be duly forwarded by the Treasurer of the Association to the hospital indicated by the donor. Another wrong impression is that, in the distribution of the collection, 25 per cent. is deducted from designated gifts; the truth being that before any distribution is made by the Distributing Committee, all designated gifts are sent in full to the hospitals for which the donors intended them. Whatever remains is known as the undesignated or general fund, which is then placed at the disposal of the Distributing Committee for division among the associated hospitals according to the free work done by each. When, however, any hospital has received in designated gifts \$1,000, or more, the Distributing Committee has

taken that fact into account, and, under the discretion given it by the Association, subtracted 25 per cent. of such designated gifts from the sum which would otherwise come to such hospital as its proportion of the undesignated fund; and the amounts thus withdrawn have been divided in equal proportions among the ten or twelve institutions receiving least from the collection." It is a matter of universal regret that the unity of the work of the Hospital Association should be broken by the withdrawal of the Presbyterian Hospital, especially for such a cause as that assigned; and, as has been pointed out, its action seems all the more extraordinary when it is found to be a fact that it reports this year \$11,000 more annual income from invested funds than does St. Luke's, and that its income last year was considerably in excess of its reported expenditures.

APHEMIA.

This word has been sometimes used as synonymous with aphasia, but its signification is more correctly limited to the loss, more or less complete, of the memory of the co-ordinated movements necessary for the articulation of words. The word aphasia is now used in a more generic sense as the amnesia of signs, and includes as species, aphemia, sometimes called motor aphasia, as also word-blindness, word-deafness, and agraphia, (sensorial aphasia). Among the synonyms of aphemia the following are in use by various authorities: *logoplegia* (Jacquard), *laloplegia* (Lichtenstein), *ataxic aphasia* (Kussmaul) *amnesionomia* (Piorry), *verbalparalysis* (Tamburini).

This is the classical form of aphasia, and has an interesting history in connection with the first scientific attempts at cerebral localization. Sixty-two years ago Bouillaud understood and described this motor aphasia, which he recognized as independent of all lesion of the external organs of articulation and the nerve cords which connect them with the cerebrum, and which he attributed to a destroying lesion of the cerebral organ which co-ordinates the divers movements concerned in articulation. "It is," according to Bouillaud, "a loss of memory which does not deprive its victims of the faculty of expressing their ideas and desires by other signs than spoken language, such as gesture and writing."¹

Broca's original description of this affection² will still pass as current coin; and to this physiologist science is most deeply indebted for the direction and precision which have been given to studies in this department of psycho-physiology and pathology. It was Broca who first designated this peculiar speech-paralysis by the name aphemia:

"There are cases where the general faculty of language remains unaltered, where the apparatus of hearing is unimpaired, where all the muscles of articula-

¹ Bouillaud, Clinical and Physiological Treatise on the Encephalon. Paris, 1825.

² Broca. Bull. de la Soc. Anatom. de Paris. 1861, 2d Serie, T. vi, p. 359.

tion are intact, and yet, where a cerebral lesion has abolished the power of articulate language. . . . These patients hear and understand what is said to them; their intelligence does not seem to be seriously, if at all, impaired; they emit vocal sounds readily, and yet the only utterance which they can give to their thoughts or desires, or in response to questions, is limited to a very few words, sometimes monosyllables, which may have no relevance to the ideas which they wish to communicate. Some have lost every vestige of articulate language, and cannot utter a syllable. . . . The language which they formerly spoke is always familiar to them, but they cannot execute the series of methodical and co-ordinated movements which correspond to the word or phrase sought for."

This is unquestionably the most common and the most easily recognized form of aphasia, and every physician in general practice is continually seeing instances, generally, it is true, in connection with right-sided hemiplegia, but sometimes as an isolated affection. The following is one of Broca's typical cases, as cited by Kussmaul.³

"A man eighty-four years of age, by name Le Long, had an apoplexy, with unconsciousness, one year and a half before his death. Aphasia remained as a sequence until the end, aphasia, without any other paralysis whatever, with good intelligence, good memory, and good comprehension. He performed properly all voluntary movements of the tongue, lips, etc., and could make himself comprehensible to others by means of gestures and five words, which he uttered somewhat indistinctly although he was able to articulate distinctly the sounds of which they were composed. . . . He had at his disposal only those five words, with which he supplemented his very expressive gestures: *oui*, *non*, *trois* instead of *trois*, *toujours* and *Le Lo* instead of *Le Long* - that is, three perfect and two mutilated words. He affirmed with *oui*, and denied with *non*; for all numbers he employed *trois*, indicating the exact number which he had in his mind by an adroit use of his fingers; he used the word *toujours* when he could not indicate his meaning by any of the other words."

In the description above cited it is said that the intelligence of these patients does not seem to be much, if at all, impaired; they appreciate the meaning of spoken words from the fact that the cohesion between sound and meaning is unimpaired in aphemia, it being the cohesion between sound and articulation which is broken.⁴ It is certain, however, that in all cases of aphasia there is a greater or less degree of enfeeblement of the intelligence which makes itself manifest when the proper tests are applied. The true aphasic finds it difficult to grasp an abstract idea, command the attention, or sustain any intellectual effort.⁵

As for the anatomical situation of the lesion which causes motor aphasia, pathologists are attaining clearer light and greater certainty as the years roll by, since first Gall located the *word-sense* and the *speech-sense* in the frontal lobes (1810-1819); since first Bouillaud announced as the result of over five hundred autopsies, that the speech centre was in the anterior lobes of the cerebrum (1825); since Marc Dax in 1836, proclaimed the constant occurrence of disturbances of speech with lesions of the left hemisphere, and Broca, in 1861,

came forward with his epoch making discovery of the concomitance (he regarded it as the invariable concomitance), of motor aphasia, with lesions of the third frontal convolution on the left side, more particularly with lesions of the posterior third of that convolution. Broca's proposition which has been confirmed by thousands of careful observations, and which is now admitted by physiologists as a general law, to which there are few exceptions, is, that the development and exercise of the speech-function is dependent on integrity of the left frontal convolution. We say *few exceptions*, for doubtless in left-handed persons the corresponding gyrus on the right side is the one on which devolves the co-ordination of speech movements, as appears from the findings of numerous autopsies in left-handed aphasics; moreover, we do not think that science, is yet in condition to affirm that in rare cases parts in the vicinity of Broca's convolution (the insula, gray matter bordering the fissure of Sylvius posterior to the third frontal, etc.), may not contain the centres concerned in word-ideation and word-execution. This is, however, certain, that much that has been in times past alleged in opposition to Broca's localization is vitiated and rendered inconclusive by defective observation. This was especially true the first five years after the announcement of Broca's discovery and during the unprecedented storm of opposition with which that announcement was greeted: even Trousseau was caught tripping by Broca himself, who found a spot of softening in a post-mortem specimen, which the former had overlooked,⁶ and Charcot, in a remarkable case which first seemed to bear against Broca's doctrine, afterwards acknowledged that it gave support thereto - though Broca's centre was intact, a portion of the centrum ovale underneath it, and a part of the internal capsule constituting the inferior pediculo-frontal fasciculus were destroyed.⁷ In fact, no observation against the above-mentioned localization is valid, unless in a given case of aphasia, supposed to contradict such localization, it be shown that, along with integrity of the third left frontal, there was also integrity of the nerve fibres proceeding therefrom, and of the underlying structures. For it is clear that a clot of blood, a neoplasm, or other cause, which interrupts the continuity of the fibres proceeding from a nerve centre, will just as surely paralyze the function of that centre as an immediate lesion thereof.

In fine, the essential importance of the posterior extremity of the third left frontal convolution for the exercise of the function of speech remains, in the language of Nothnagel, at the late Congress of Internal Medicine, at Wiesbaden, as also of his co-reporter Naunyn, "unattackable,"⁸ and we may conclude that the association of aphemia with lesion of Broca's centre is so constant, that the clinical observer in presence of a case of motor aphasia is justified in making an almost absolute diagnosis as to the seat of the trouble.

THE TREATMENT OF HERNIA.

SINCE 1803 the management of the Boston Dispensary have furnished trusses to those patients whose power of earning a subsistence depended upon their wearing this instrument. The trustees of this institution, mindful of the benefit which this custom has conferred upon the poor, have determined to establish a special department for the treatment of all forms of hernia.

Of the many charitable organizations in this country for the relief of human suffering, but very few include in their forms of aid the supply of trusses. Certainly no class of people can possess a stronger claim for consideration than those who suffer from hernia, both because of their large number and the peculiar nature of their affliction.

Societies have been established in this country and abroad—notably in London and in New York—for the treatment of this disability. In the former city there are two societies whose sole purpose is the relief of the ruptured poor. The National Truss Society, established one hundred years ago, provided 1,401 trusses for its patients during 1886. The London Truss Society, which has existed for eighty years, furnished, during 1886, 9,372 trusses. The New York Society for the relief of the Ruptured and Crippled, founded twenty-four years ago, supplied trusses, during the year 1886, to 4,061 patients.

The importance of this form of relief cannot be too strongly emphasized. The frequency of hernia, and the disastrous results which follow from its neglect, or from improper treatment are familiar facts. To supply a patient with a truss is by no means sufficient. The truss must be adapted to the peculiarities of each individual case, and this involves anatomical knowledge to diagnose, and skill, together with mechanical ingenuity, to treat.

It is certainly time that the application of trusses should be taken out of the hands of ignorant laymen and pseudo-doctors, and placed, as the application of orthopaedic instruments has been, in more highly educated and discriminating hands.

OFFICIAL REPORT ON THE NEW YORK QUARANTINE STATION.

THE State Board of Health, under the date of December 10th, made a report to the Governor of its investigation into the recent outbreak of cholera at Quarantine, New York Harbor, which has only just been made public. Much of the testimony on which the report is based was furnished by Dr. Balch, the secretary and executive officer of the board, who made a personal examination of the Quarantine Station; but this has been amply corroborated by trustworthy evidence collected by the president of the board, Mr. Newbold.

The result of the investigation is abundantly confirmatory of the developments brought to light by the

committee of the College of Physicians, of Philadelphia, and the nature of the report may be inferred from the following extract: "It is the unanimous opinion of those posted on such matters that it would be difficult to imagine a worse state of affairs than now exists at the Quarantine Station. It is hard to realize in this age of civilization that the harbor of the city of New York should be so inadequately provided with facilities for the prevention and extinction of an epidemic." The serious defects of the Health Officer's administration are clearly set forth, and it is shown that Dr. Smith's work was not regarded as satisfactory by the health authorities of the city; while the changes for the better which were made after the arrival of the *Britannia* were plainly the result of suggestions from physicians and experts by whom the station had been inspected. Such a report, it is to be hoped, will have some effect even on a New York Legislature, and induce it to put an end to a condition of affairs so disgraceful to the State. Governor Hill has more than once made a good appointment for Dr. Smith's position; but the legislature, for political reasons, has always refused to confirm it.

MEDICAL NOTES.

—Cholera existed at the close of the year in Sardinia. There has also been a moderate increase of the disease in Chili, and the Peruvian Government has closed its ports against all shipping from the Chilean republic.

—Dr. Roux, surgeon of the Cantonal Hospital in Lausanne, recently administered two six-gramme doses of extract of male-fern to a girl of twenty-one, and obtained as a result ninety bothrioccephali lat. The delivery of this mass was as might be supposed, rather a serious thing for the girl, and the counting of the parasites was also a serious thing for the doctor, occupying as it did, four and one-half hours.

—Dr. Norman Bridge, one of the attending physicians to Cook County Hospital, recently refused to treat as charity patients persons able to pay, but admitted to the hospital under political favoritism, and for his refusal was severely criticised by the *Chicago Tribune*.

—The *Medical News* reports a revolt of venereal patients in the hospital of Santa Maria, at Naples, where a number of women suffering from specific diseases are under treatment and the authorities had forbidden the friends and paramours of the patients from calling upon them. This was followed by an open revolt for eight hours, during which the furniture of the hospital was demolished, windows and doors broken, and twenty-two of the Sisters of Charity in attendance were injured more or less severely. The patients attacked the police, and wounded several. Order was finally restored, and twenty-eight arrests were made. A reform in hospital management is evidently needed.

BOSTON AND NEW ENGLAND.

— The will of the late William Hilton, which was filed in the probate office for Suffolk county last week, provided for the ultimate distribution of almost half-a-million dollars among various charitable and religious institutions. Among them, those of special interest to medical readers, are the Massachusetts General Hospital, which is to receive \$50,000, to be invested as a separate fund and called the "William Hilton fund," the income to be applied for the support of free beds. The Boston Dispensary, \$50,000, the income to be used for the purposes of the institution. The Children's Hospital, \$10,000. Harvard, Amherst and Williams Colleges, and Phillips Academy, Andover, also get \$50,000 each.

— The new City Hospital of Haverhill was dedicated and formally opened on the 29th of December. The late Hon. E. J. M. Hale gave, in 1882, \$50,000 and a site for the building. To this was added a generous gift by Mr. James H. Carleton in 1886, which greatly hastened its completion. The site for the institution, which was substituted for the one first indicated, is a gift of Mr. Carleton, and located in the picturesque region of Lake Kenosha. The trustees of this institution are the Mayor, ex-officio, Nathan S. Kimball, Samuel M. Currier, Addison B. Jacques, Amos A. Sargent, Samuel K. Towle, and John Crowell. The medical staff consists of Drs. O. D. Cheney, Maurice D. Clark, John F. Croston, W. D. Holden, L. J. Young, and G. C. Clement. The consulting physicians are James C. How, Ira E. Chase, Oliver S. Lovejoy, Otis H. Johnson, and William D. Collins. The superintendent is Mr. James F. Drew, and the matron Mrs. J. F. Drew.

The exercises of the dedication consisted of an opening address by His Honor, Joseph H. Sheldon, Mayor; historical sketch by John Crowell, M.D.; prayer by Rev. A. Boynton; address by O. D. Cheney, M.D.; a letter read from Samuel K. Towle, M.D., a trustee, now surgeon of the National Soldier's Home, Virginia; singing by the Alpine quartet. Dr. John Crowell delivered an able and interesting address, giving the history of the inception and progress of the undertaking.

— Since the middle of August a malignant type of diphtheria has been prevalent in Pittsfield, Mass. The local Board of Health think twenty-three of the cases may fairly be traced to one milk route. The milk farm supplying this route, though apparently in excellent condition, has voluntarily given up its business. The sanitary arrangements of one of the school-houses have been found to be so bad that the building has been closed. The State Board of Health has been appealed to for advice.

NEW YORK.

— A Burial Reform Association has recently been organized under the auspices of the Protestant Episcopal Church, although it is intended that it shall be undenominational in character. Among the reformatory measures which it seeks to carry out are the following:

The exercise of economy and simplicity in everything pertaining to funerals.

The early interment of the body in soil suitable for its prompt resolution into its ultimate elements.

The use of such material for the coffin as will rapidly decay after burial.

The substitution of burial plots for family vaults. The encouragement, on sanitary grounds, of the removal, in crowded districts, of the body to a mortuary, instead of retaining it in rooms occupied by the living.

— On the 19th of December, a boy died at the New York Dispensary from heart-failure resulting from shock due to loss of blood after having a tooth extracted. Uncontrollable hæmorrhage followed the drawing of the tooth, and death followed in twenty minutes. The physicians at the Dispensary expressed the opinion that the lad was the subject of hæmophilia.

— The Board of Estimate and Apportionment have made an appropriation for the expenditures of the Commissioners of Charities and Correction for the coming year considerably in excess of the amount allowed for 1887, in order to carry out some of the reforms in the management of the institutions for the insane under the care of the department which the investigation of the Board of State Charities, last summer, showed to be needed.

— The City Board of Health having received a communication or letter from the Captain-General of Cuba to the effect that small-pox was raging in Cuba, and that the supply of vaccine virus had become exhausted, referred the matter to Dr. Edson, Chief of the Bureau of Contagious Diseases, who, on December 24th, shipped to Havana three fine, healthy, vaccinated calves for the propagation of virus.

— On the occasion of the formal opening, December 29th, of the Sloane Maternity Hospital and the Vanderbilt Clinic, in connection with the College of Physicians and Surgeons, Dr. T. Gaillard Thomas made the principal address.

— Among the numerous charitable bequests in the will of the late Mrs. John Jacob Astor, are included \$25,000 each to the Women's Hospital and St. Luke's Hospital.

CHICAGO.

CHICAGO AS A MEDICAL CENTRE.

— *Chicago is something of a medical centre.* It is doubtful if the profession of the East fully understand this fact. There are no less than eleven schools of medicine in town, of one sort or another, that are of the regular profession, or are recognized by the State Board of Health. Four of these are regular medical colleges, diplomas from which now qualify for practice before the State Board, although the Board has declared that after 1890 neither the diplomas of these nor of any other colleges will be accepted that do not require four years of study and three full courses of lectures. These colleges are: *Rush*, the oldest and largest, nearly fifty years of age

(the oldest educational institution in the State, its friends enjoy saying); the *Chicago*, now approaching thirty years of age; the *College of Physicians and Surgeons*, the youngest of them all; and the *Woman's*, which is about eighteen years old. The last named is a woman's college, as all the others admit only men. *Chicago College* tried the experiment, before the *Woman's* was founded, of admitting female students, but the experiment did not work well, and it was promptly abandoned at the end of a single term.

The *Chicago College* has been a department of the Northwestern University for many years. *Rush College* has recently become the medical department of the Lake Forest University, near Chicago, an institution under the control of the Presbyterian order. These regular schools may be said to be in a prosperous condition, if the fact of their graduating a total of nearly or quite three hundred persons annually may be taken as evidence of prosperity.

There are two homeopathic colleges and one of the so-called eclectic school. Of these three, the original and first homeopathic school is the most prosperous; it probably graduates as many pupils as the other two combined. This school boasts that it teaches the "Simon pure" article of homeopathy, while its rival teaches a mongrel between this and regular medicine.

There are two regularly chartered schools for practitioners, covering the entire practical field of medicine. These are the *Chicago Polyclinic* and the *Post-Graduate School of Medicine*; the former continues its instruction throughout the year, the latter only for three months of the summer. The number of pupils in these schools is always small, but the organizations are over two years old, and their managers declare they are here to stay. In each the habit of Eastern schools of this kind, of dividing the year into periods or courses of six weeks each, is pursued.

Then, in addition to this formidable array of opportunities, there are two chartered schools for instruction in the specialties: one the *Chicago School of Dermatology*, the other the *Chicago Ophthalmic College*. The former has a faculty of five professors, the latter one of eleven professors. The former offers to cover, in addition to dermatology, the fields of genito-urinary, renal, and rectal diseases; the latter teaches only ophthalmology, otology, and laryngology, and both admit only practitioners.

In addition to this long list of strictly medical schools, there are here no less than four schools of dentistry, all of which have sprung up within five years. The first was the *Chicago College of Dental Surgery*, which started out to teach only medical graduates to be dentists, the laudable purpose being to make dentistry a department and specialty of medicine. But the number of students of the sort admitted was too small, and the plan was, after a couple of years, changed to that of an ordinary dental college. The other schools have been organized since. One of these newer acquisitions is a department of the Northwestern University, another of the Lake Forest.

Each school gives instruction in anatomy, physiology, materia medica, and chemistry—it is alleged, as thoroughly as any medical college—in addition to the strictly dental studies. The branches referred to are taught by medical men, and each one is a professor.

Chicago is really a paradise of professors. Among all the schools above referred to, there are not less than one hundred professors who are medical practitioners—to say nothing of the dentists—and a few hold chairs in two or more institutions. The lowliness of fees and other circumstances compel most of these doctors to perform their professional duties *gratis*—probably not a third of them receive a compensation from their schools that can be called more than nominal. In addition to the professors, are more than half as many lecturers, demonstrators, and other instructors who are practitioners of medicine, a large majority of whom receive no compensation. Perhaps in no other city of its size is more unpaid instruction in medicine given by so large a number of men as in Chicago.

To add to the character of the city as a centre of medical study, seven of the medical schools are located within a quarter of a mile of the large public hospital, the Cook County, and two other hospitals (the Hospital for Women and Children and the Presbyterian) are not farther away. Another of the schools, the *Chicago Medical*, is within easy reach of the Mercy, the Michael-Reese, and the St. Luke's Hospitals.

Now, we are aware that the criticism of the East would be, and is, that all this medical teaching is hurried, crude, and lacking in thoroughness, and that out of it all there is not a sufficient addition to the stock of knowledge—not sufficient investigation and research. To the first charge we plead not guilty. As teaching schools, there is no doubt most of these institutions are successful in a high degree, and their graduates, as practical men and successful practitioners, rank well. To the second charge, the reply is that it is true, but is, has been for several years past, and is going to be in the future, less and less true as time passes. It is a fact that there is not here a chair in any of the schools, or a laboratory of any sort that is endowed; there is no endowment of research. But the hopeful and thoughtful members of our profession do not believe it will always or long be so; our millionaires, and they are numerous, will not forever be wrapped up in pork, grain, dry goods, stocks, and railroads; indeed, the evidence of this truth is already apparent in some handsome endowments of institutions not medical. Medical research seems to be about the last thing to be endowed.

An encouraging sign is the fact that more careful study and investigation in a private way are being done each year. Another matter for congratulation is the starting of the great Newberry Library, under the directing hand of Mr. Poole. It is expected that it will be especially a library for students, and there must be a large corner and outlay for medicine.

Miscellany.

PILOCARPINE IN ACUTE AFFECTIONS OF THE RESPIRATORY ORGANS.

IN certain acute affections of the respiratory organs, Dr. Wyss, as quoted by the *Medical Record*, has given small doses of pilocarpine, as one-sixth of a grain, with decided benefit. A case of acute coryza is reported, with intense congestion and swelling of the conjunctiva and nares, and pharyngeal dryness. Recovery in three days under the use of one-sixth of a grain of pilocarpine at bed-time. An acute attack of laryngitis in another patient with loss of voice was similarly benefited. A man, aged forty-four, suffering from acute pharyngo-laryngitis with frequent attacks of suffocation from oedematous swelling. Experienced marked relief with restoration of voice after the first dose of pilocarpine taken at bed-time, and had no more attacks of suffocation. A case of acute laryngo-bronchitis with violent dyspnoea and labored respiration was speedily relieved by a quarter-of-a-grain dose at bed-time, and another of bronchitic asthma and hypertrophic rhinitis was similarly benefited by one nightly dose of a sixth-of-a-grain. This patient, who had been for many years a great sufferer from asthmatic attacks, stated that no other remedy had ever given her such rapid and permanent relief.

Dr. Wyss prescribes pilocarpine as follows:

R Hydrochlorate of pilocarpine . . . half a grain.
Distilled water . . . three ounces.
To be divided into two or three equal parts by the graduation of the phial. Or this one-half or one-third is to be taken directly after having retired to bed.

THE DANGERS OF DUSTS.

A PAPER was read by Dr. Henri Napias, before the Congress of Industrial Hygiene, held at Rouen, on the dusts developed in industries and the method of guarding against injury from them, of which we find the following abstract in *Building*:

Dusts in the air call for especial consideration, from the fact that, besides vitiating the atmosphere in the way that gaseous impurities also do, they exert a mechanical action when brought in contact with the respiratory and digestive systems.

Even when they are wholly toxic or essentially irritant effects, they are foreign bodies and obstructive, and are always in danger of exerting a traumatic action or causing abrasions. They are, therefore, all dangerous, while the dangers arising from them may be various in character. Mineral dusts, whether of stones or of metals, are the most dangerous, because, besides being hard and sharp, and liable to cut the tissues, very many of them are also poisonous or caustic.

Dusts of organic origin are less dangerous, but they vitiate the air, communicate unpleasant qualities to it if they are of an animal nature, and are frequently vehicles for the conveyance of infectious germs. Various inconvenient affections of the lungs are caused by breathing these dusts, among which may be counted phthisis, not as produced directly by them, but as often ultimately induced by the abrasions or deterioration of the tissues which they immediately occasion.

The readiest and most available means of removing dusts is by ventilation, and when this can be so di-

rected as to take them away as soon as they are formed, it is almost sovereign. It will not do, however, to rely upon general ventilation, for that will at most remove the dusts but imperfectly, while its usual operation will be more likely to distribute them more widely among the operatives.

The remedy should be applied to light dusts by means of chimneys or draught-flues; and to the heavier ones by means of blasts to drive them away. In cases where the dust itself is the object of the manufacture, or is to be applied in the manufacture, the remedy is to conduct the processes in closed apparatus. When either method is practicable, the dust may be kept down or removed by water, or the articles may be worked in a moist condition.

Some workmen employ masks or respirators as means of individual protection, and they may in some processes be the only efficient means available. They are liable to the objection that they are always cumbersome and inconvenient; and frequently the workmen will become careless about them, or refuse to be bothered with them, and will leave them off. They should not be depended upon when any practical means of keeping down or removing the dust can be employed.

TREATMENT OF INTESTINAL INVAGINATION IN CHILDREN.

HERZ has written on the above subject (in the *Arch. di. Pitol. Inf.* for May, 1887), and a *résumé* of his paper is given in the *Archives of Pediatrics*, November, 1887. It is believed by the author that in many cases of intestinal invagination spontaneous reduction will take place if the patient is relaxed by anesthetization, or at most with the use of moderate taxis. Should the case be rebellious to such means, a large volume of air should be injected into the intestine, to be followed, if necessary, by a sufficient quantity of water. The more recent the invagination and the lower in the abdominal cavity its situation, the better will be the chances of success. The child should be placed upon his back with the knees bent, and a gum-elastic catheter should be introduced as far as possible. Through this the air should be slowly forced for about two minutes; during the intervals of injection massage being mildly practised over the supposed seat of invagination. If water is to be injected, a warm bath should first be given, lasting half an hour. The child should then be anesthetized, the head and shoulders being on a higher plane than the abdominal cavity, and three or four litres of water slowly and gently injected, the greatest care being taken to avoid rupturing the intestine. Instead of three or four litres of water at the ordinary temperature, a single litre of very cold water may be used. Should these means prove unavailing, the only resource remaining is laparotomy.

OBITUARY. JAMES R. NICHOLS, M.A., M.D.

Dr. James R. Nichols died at Haverhill, Mass., January 2d. He was born in West Amesbury, now Merrimack, Mass., July 19, 1819. He had many advantages for acquiring an education, attending the district school but one term during the winter. But by dint of especial effort in his leisure hours, he gained a practical knowledge as apothecary's clerk, which led to his subsequent high reputation as a chemist.

At twenty-two he commenced to study the theory and prac-

tice of medicine under Dr. Randall Flint, of Haverhill, and after he attended the medical lectures at Dartmouth College. He received his M.D. diploma at that institution in 1867, joining the Massachusetts Medical Society the same year, and subsequently received the honorary degree of M.A. He engaged in the drug business on his own account in 1843, but continued his researches in chemistry previously begun, and which at that time was just beginning its development. He soon became an experimenter and investigator in all the new discoveries of the times, which gave him a wide reputation through his writings and lectures.

After an extended European tour in 1867, during which he acquainted himself with many workers in the field of industrial chemistry, he established himself in Boston as a manufacturing chemist under the firm name of James R. Nichols & Co. This firm early carried on an extensive business in all parts of the country, and was the first to manufacture the finer class of chemicals, such as had previously been imported from Europe.

Dr. Nichols established the *Journal of Chemistry* in Boston, in 1865, and had ever since continued to edit it. This journal holds a high place in its special field, having more recently

been called the *Popular Science News*. He revisited Europe in 1872, and on his return, relinquished business in Boston and returned to Haverhill, where he has since resided.

In 1878, Governor Rice appointed him a member of the State Board of Agriculture. He was always identified with agricultural affairs, and published many important papers treating on the subject.

Dr. Nichols was the author of three well-known works, the first two of which were published prior to 1872—"Fireside Science," and "Chemistry of the Farm." The last, entitled "Whence, What, Where," was published in 1883, and has thus far reached its eleventh edition.

Dr. Nichols was twice married. His first wife was a daughter of E. A. Porter, of Haverhill, whom he married in 1844. He formed a second union with a daughter of the late James Cole, in 1851, by whom he had two children, of whom one, a son, succeeds him as editor of the *Popular Science News*, and the other, a daughter, is the wife of Mr. J. G. Cupples, one of the publishers of this JOURNAL. Dr. Nichols founded a public library in his native town of Merrimac, in 1878. His own private library is one of the largest and most valuable in the State.

REPORTED MORTALITY FOR THE WEEK ENDING DECEMBER 21, 1887.

Cities.	Estimated Population.	Reported Deaths in each.	Deaths under Five Years.	Percentage of Deaths from

Deaths reported 2,251: under five years of age 802; principal infectious diseases (small-pox, measles, diphtheria and croup, diarrheal diseases, whooping-cough, erysipelas and fevers) 436; consumption 302; acute lung diseases 306; diphtheria and croup, 208; scarlet fever 67; typhoid fever 40; diarrheal diseases 35; malarial fever 24; measles 19; whooping-cough 12; cerebro-spinal meningitis 11; erysipelas 11; puerperal fever seven; small-pox two. From diarrheal diseases New York 15, Philadelphia six, Brooklyn, Baltimore, Nashville and Fall River two each, Boston, District of Columbia, Pittsburgh, Charleston and Somerville one each. From malarial fever, New York nine, Brooklyn six, New Orleans five, Baltimore four. From measles, Baltimore eight, New York six, District of Columbia two, Brooklyn and Boston one each. From whooping-cough, New York three and Boston three each, Philadelphia, Brooklyn, Pittsburgh, Milwaukee, Charleston and Waltham one each. From cerebro-spinal meningitis, New York five, Milwaukee two, New Orleans, District of Columbia, Lynn and Somerville one each.

From erysipelas Brooklyn five, New York three, Philadelphia, Baltimore and Worcester one each. From puerperal fever, Pittsburgh two, New York, Boston, Milwaukee, Charleston and Cambridge one each. From small-pox New York and Brooklyn one each.

In the 28 greater towns of England and Wales with an estimated population of 9,244,089, for the week ending December 10th, the death-rate was 21.1. Deaths reported 3,746; infants under one year of age 831; acute diseases of the respiratory organs (London) 408; whooping-cough 116; scarlet fever 91; fever 77; measles 73; diphtheria 44; diarrheal 27; small-pox (Sheffield 17, Bristol two, Hull one) 20.

The death-rates ranged from 15.6 in Plymouth to 33.2 in Newcastle-on-Tyne; Birkenhead 19.8; Birmingham 23.1; Hull 17.5; Liverpool 22.4; Leicester 20.6; Liverpool 19.4; London 19.5; Manchester 29.2; Nottingham 20.9; Sheffield 23.8; Sunderland 17.7.

In Edinburgh 21.1; Glasgow 24.0; Dublin 35.6.

The meteorological record for the week ending December 24, in Boston, was as follows, according to observations furnished by Sergeant O. B. Cole, of the United States Signal Corps:—

Week ending	Barom-eter.		Thermometer.		Relative Humidity.			Direction of Wind.			Velocity of Wind.			State of Weather. ¹			Rainfall.		
	Daily Mean.	Daily Minu.	Maximum.	Minimum.	7.00 A. M.	3.00 P. M.	10.00 P. M.	7.00 A. M.	3.00 P. M.	10.00 P. M.	7.00 A. M.	3.00 P. M.	10.00 P. M.	7.00 A. M.	3.00 P. M.	10.00 P. M.	Duration Hrs. & Min.	Amount in Inches.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM DECEMBER 24, 1887, TO DECEMBER 30, 1887.

BAXTER, J. H., colonel and chief medical purveyor. Ordered to inspect the medical purveyor depot at St. Louis, Mo. S. O. 296, A. G. O., December 23, 1887.

BAXISTER, Wm. D., first lieutenant and assistant surgeon. Ordered to proceed to Fort Lowell, Arizona, and report to commanding officer for duty upon the arrival of Surgeon P. J. A. Cleary, at Fort Wingate, New Mexico. S. O. 135, Department of Arizona, December 20, 1887.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE UNITED STATES NAVY DURING THE WEEK ENDING DECEMBER 31, 1887.

BIDDLE, C., passed assistant surgeon. Detached from the Marine Hospital, Philadelphia, and placed on waiting orders.

CLEBERG, C. J., medical director. Detached as member of medical examining board December 31st, and ordered to Norfolk Naval Hospital, January 5, 1888.

BRADLEY, M., medical inspector. Detached from Naval Hospital, Norfolk, January 5, 1888, and placed on waiting orders.

CLARK, J. H., medical inspector. Detached from special duty at Portsmouth, N. H., and ordered as member of examining board at Washington.

SOCIETY NOTICES.

MASSACHUSETTS DENTAL SOCIETY.—At the meeting of the Massachusetts Dental Society, December 2, 1887, the following officers were elected: President, H. C. Meriam, Salem, Mass.; first vice-president, G. A. Gerry, Lowell, Mass.; second vice-president, R. R. Andrews, Cambridge, Mass.; secretary, G. F. Farnes, 62 Trinity Terrace, Boston; treasurer, E. Page, Boston; executive committee, E. B. Hitchcock, A. H. Gilson, W. E. Page, J. K. Knight, E. C. Leach.

MASSACHUSETTS MEDICAL SOCIETY, SUFFOLK DISTRICT.—THE SECTION FOR CLINICAL MEDICINE, PATHOLOGY AND HYGIENE will meet at 19 Boylston Place, on Wednesday, January 11th, at 7.45 o'clock. Papers: Dr. W. N. Bullard, "A Case of Cerebral Localization with Double Trephining." Drs. E. H. Bradford, J. J. Putnam, and Morton Prince will open the discussion. Dr. George B. Shattuck, A case of "Hereditary Locomotor Ataxia (Friedreich's Disease)." Dr. Henry Jackson, "Fifty Cases of Scarlet Fever."

A. L. MASON, M.D., Chairman.

ALBERT N. BLODGETT, M.D., Secretary.

GYNECOLOGICAL SOCIETY OF BOSTON. The annual meeting of the Society will be held at the Medical Library Rooms, No. 19 Boylston Place, on Thursday, January 12th, at 4 o'clock, P.M. Program: President's Annual Address, by Dr. H. C. White. Annual election of officers. A collation will be served after the exercises.

H. J. HARRIMAN, M.D., Secretary.

APPOINTMENTS.

The following appointments have been made at the Carney Hospital, January 1, 1888: Dr. Drumcey, Senior House Officer;

Dr. Walker Foley, Junior House Officer; Mr. J. P. Gaffney, Assistant Intern; and Messrs. W. S. Beaumont and Giblin, for out-patient assistants.

PRIZES FOR ESSAYS ON MEDICO-LEGAL SUBJECTS.

The Medico-Legal Society of New York announces the following prizes for original essays on any subject within the domain of medical jurisprudence or Forensic Medicine:

1. For the best essay—one hundred dollars, to be known as the Eliot F. Shepard Prize.

2. For the second best essay—seventy-five dollars.

3. For the third best essay—fifty dollars.

The prizes to be awarded by a commission, to be named by the President of the Society, which will be hereafter announced. Competition will be limited to active, honorary and corresponding members of the Society at the time the award is made.

It is intended to make these prizes open to all students of Forensic Medicine throughout the world, as all competitors may apply for membership in the Society, which now has active members in most of the American States, in Canada and in many foreign countries.

57 Broadway, N. Y.

CLARK BELL, Secretary.

DEATHS.

Died in Wilmington, N. C., December 31, 1887, Edward Emerson Swallow, M.D., M.M.S.S., late of Waltham, Mass., aged thirty-four years.

In Haverhill, Mass., January 2, 1888, James Robinson Nichols, M.D., M.M.S.S., aged sixty-eight years.

BOOKS AND PAMPHLETS RECEIVED.

Wounds, Their Aseptic and Antiseptic Management. By David Prince, M.D., Jacksonville, Ill. 1887.

The Radical Treatment of Trachoma. By A. E. Prince, M.D., Oculist to Wabash Hospital and State Institution for Deaf and Dumb and Blind. Reprint.

Proceedings of the Connecticut Medical Society, 1887. Ninety-sixth Annual Convention, held at Hartford, May 25th and 26th. New Series. Volume III. No. 4. S. B. St. John, M.D., Secretary.

Forms for Systematically Recording Observations and Results of Treatment in Affections of the Throat and Nose, Including Adjacent Associated Areas. By Scanes Spicer, M.D., B. Sc. London: H. K. Lewis. 1887.

Report of the New York Post-Graduate Hospital, Including the Babies' Ward. Founded February 1, 1884. For the Year Ending May 1, 1887.

Medical Lectures and Essays. By George Johnson, M.D., F.R.S., etc. London: J. & A. Churchill. 1887.

Report of the Surgeon-General of the Army to the Secretary of War for the fiscal year ending June 30, 1887. Washington, 1887.

The Treatment of Uterine Fibroids by Electrolysis. By W. E. Stevenson, M.D. Cantab., M.R.C.P., in charge of the Electrical Department at St. Bartholomew's Hospital; Physician to the Grosvenor Hospital for Women and Children. London: J. & A. Churchill. 1887.

Lecture.

THE HISTORY OF MEDICINE.

INTRODUCTORY LECTURE.¹

BY J. S. BILLINGS, M.D., LL.D. (HARV.) SURGEON, U. S. A.

UPON the front of the new building on Boylston Street which is occupied by the Medical School of Harvard University, there are stamped ten names, arranged in two rows. The names in the upper row in the order given are: Paré, Galen, Hippocrates, Celsus, Vesalius; and those in the second row are, Haller, Harvey, Sydenham, Hunter, Bichat. You know that these are the names of men who have been specially prominent in the history of medicine — names which have a special significance to educated physicians.

At the end of this course of lectures I hope that those who have listened to them will have a clearer idea than they now have as to why these ten names were selected for that position, and how they are connected with the origin and progress of medicine considered with reference to both its scientific and its practical aspect. But while these lectures will be devoted mainly to indicating the influence which certain individuals have exercised on the progress of the healing art, it must be borne in mind that to fully understand this influence, it is not enough to consider only what physicians have said or done. As Carlyle says, action is solid while history can be only linear. To attempt to isolate the history of medicine, and to comprehend its curious ebbs and flows of doctrine, from medical writings only, is like cutting a narrow strip from the centre of a piece of tapestry and speculating upon the origin and purpose of the cut threads and fragments of patterns that may be found in it.

We cannot appreciate Hippocrates without some knowledge of the Greek schools of philosophy; we cannot understand Galen, without knowing the teachings of Plato and Aristotle; it is not possible to see why such strong opposition was made to Vesalius and Van Helmont if we know nothing of the history of Catholicism and of the Protestant reformation; and the existing differences in regard to medical legislation and education in civilized countries cannot be fully appreciated without information as to the mode of development of the polity of the several States.

Medical history, in fact includes much that belongs also to the history of philosophy, jurisprudence and science, the chief difference being that different names are used as mile-stones and guide-posts.

The origin of medicine, like that of most other arts and sciences, is to be explained from tradition and inference rather than from history. There are two classes of legends and opinions relating to this subject, corresponding to two different classes of minds or of mental action, which are essentially opposed to each other, and which correspond to the division of thinkers and writers into two great camps as expressed by the saying: "All men are born either Platonists or Aristotelians."

The first opinion, which we find as a tradition everywhere, is that medicine is of divine origin; that it was taught by the gods to men; and as this communication would of course be made to those most intimate with and specially engaged in the service of

the superior powers, it is from this point of view natural that we should, in early times, find the healing art in the hands of the priests, and connected with religious ceremonies, while, from another point of view, these last facts would be considered as the true explanation of the legend.

The second opinion includes such explanations as that given by Hippocrates, that it arose from experience of the effects of certain foods or injuries, developed at a later period, as we shall see, into the doctrine of the Empirics; and such accounts as those given by Herodotus, Strabo and Pliny, of the custom which prevailed in the earlier days of Egypt, Babylon and Rome, of taking the sick man into the street or to some public place, where all persons passing by, inquired as to the nature of his disease and gave him the benefit of their personal experience if they had any. It is added by the historians that all who saw one thus exposed were bound to approach and give their advice; and, if human nature then resembled that of the present day, it is probable that the duty was not neglected, since it was of the nature of a pleasure. According to this the custom which now prevails that every one feels it to be eminently courteous and proper to advise a person complaining of pain, a cold, etc., as to what he should do to obtain relief, is a relic of survival from Rome or Assyria. This tradition is, somewhat more probable than the first; but we can hardly suppose that physicians of some sort, by whatever name known, should be wanting in such cities as Rome and Babylon, when we find them among barbarians and wandering tribes. We usually find among these last, and among the nations of antiquity, traces of two systems of medicine and of two classes of physicians, one lay, the other sacred, corresponding to the two legends just referred to.

Let us first inquire as to the condition of medicine among savage and barbarous nations of recent times in order to obtain some positive data from which we may reason by analogy.

Here we find that the priests are usually physicians or medicine men, and are the superior practitioners who are resorted to in obscure and difficult cases, but that there are, as a rule, other persons, often women, who treat diseases with simple and natural remedies. Disease, if severe, is thought to be due to the influence of the evil eye, or to the entrance of an evil spirit into the body of the sufferer, or, if he has not contributed properly to the support of the priest, or has been guilty of disregarding his opinions in any way, his complaint is considered as due to the vengeance of an offended good deity.

The essential remedies are incantations, steam-baths, propitiatory offerings, music, noises of various kinds, and removal of the evil spirit by suction.

Abundant testimony to the truth of these statements may be obtained from authentic accounts of the North American Indians. It should be remembered, however, in examining these accounts that these tribes use the word medicine, or what is usually translated thus, in several very distinct senses. In general, it refers to that which is extraordinary or supernatural, and the medicine man is one who possesses a knowledge and control of such matters. In particular, it may mean something like spirit, for every animate, and some inanimate objects are supposed to have their own medicine or peculiar principle. When the buffalo is seen to plunge his horns into the earth, especially

¹ To a course of eight lectures before the Lowell Institute of Boston. Delivered December 27, 1887.

just before a combat, he is supposed to be making or acquiring "medicine," that is strength, like Antæus. In like manner any article or substance which produces unusual effects upon any person, sick or well, is medicine. The term is also frequently employed in a sense which can be best illustrated by an example: An Indian will undertake to do, or to refrain from doing, some particular thing for a certain specified time, as, for instance, that he will not have a firearm in his lodge, nor will he enter a lodge in which one is kept; that he will turn only to the right and never to the left; that he will not allow any one to pass between himself and a fire, or any similar observance, and this he does to make medicine. Very great importance and value is attached to the successful completion of such obligations or vows, and the medicine so made is supposed to insure good luck and prosperity. In addition to these meanings, every Indian has his own peculiar medicine charm or talisman, and sometimes there is also a tribe medicine, usually some animal or reptile, indicated by a badge or token. The medicine man is much more than a physician; he is priest, rain-maker, and minister plenipotentiary of the supernatural powers, both good and evil. The remedies used by the medicine men of the Carolina and Florida tribes as described by Lawson² and Coreal³ were conjurations, shaking of rattles and prolonged suction either by the lips or by a sort of cupping horn. Scarifications with a sharp flint were used with the cupping and the blood obtained was carefully and secretly buried, as it was supposed to contain the evil spirit—a very widespread and ancient idea.

Dr. Barnes, late Surgeon General, U. S. A., told me that the practice of the Seminole medicine men, as he observed it, consisted essentially in rubbings and strokings corresponding to what is called animal magnetism. They also had their annual purifying of the blood by purgatives and fasting, which occurred just prior to the green-corn feast.

In Schoolcraft's work on the Indian tribes are several interesting papers on aboriginal medicine, one of which is a report by Major Alvord (subsequently Paymaster-General United States Army), on the Oregon Indians, from which I abstract as follows: "In some of these tribes any child may be trained for the position of medicine man; but among the Nez Percés the position is inherited from father to son."

All the tribes have great faith in their medicine men, and believe that they have the power of killing by charms and enchantments, and when, as sometimes happens, a man becomes possessed with the idea that the medicine man is hostile to him, and is "making medicine" against him, he will pine away, refuse to eat, and die of hypochondria and melancholy.

The consequence of this implicit faith is that when a death occurs it is often attributed to the doctor, and the relatives of the deceased avenge his fate by killing the supposed murderer. "Three doctors (says Major Alvord) have been killed for this reason within the last four months in different tribes within forty miles of this post." I cannot learn, however, that this custom has operated in deterring students from entering the profession. The tribes have women doctors also, but these sorceresses are not so much feared, and are not held so strictly responsible for results as are the medicine men.

The faith of the Oregon tribes led, in 1847, to the massacre of Dr. Whitman and others in the Presbyterian mission in the Cayuse Country, because in an epidemic of measles many died under Dr. Whitman's treatment, since they would, contrary to his directions, plunge into the icy-cold mountain streams in the height of the disease; and the war thus commenced lasted for two years.

Father Heckeewelder, in his careful and reliable account of the Six Nations,⁴ states that among them there are two sorts of doctors, one which used herbs, roots, and the sweatoven, and had no superstitious notions except that when an emetic is to be administered the water in which the potion is to be mixed must be drawn up a stream, and, if it is for a cathartic, down the stream.⁵ The second class are the usual medicine men, or priests, who attribute disease to witchcraft, and frighten it away by grotesque dresses, incantations and horrible noises.

Hunter,⁶ in his account of the medicine of the Osages, also refers to two classes of medicine men, and gives a list of the medicines used by the lay physicians, which is of interest.

Bancroft, in his work on the native races of the Pacific States, has collected accounts of their medical customs from which may be quoted the following (Vol. I, p. 418): "The California Indians for all complaints put forth the charm of woven peaces and of waving bands. The medicine men fare better than their northern brethren, as the death of the patient is attributed to the anger of the god, and consequently the physician is not held responsible. The temascal, or sweat-house, is the same here as elsewhere."

Very wonderful statements as to the powers of the Indian medicine man have been reported, as, for instance, in a paper in the *Atlantic Monthly* for July, 1866, by J. M. Browne, who resided for some time among the Blackfoot tribe. Among other things he tells of a contest between two rival medicine men which occurred among the Assiniboines in 1855.

"The rival medicine men, each furnished with his medicine bag, his amulets, and other professional paraphernalia, arrayed in full dress and covered with war-paint, met in the presence of a great concourse. Both had prepared for the encounter by long fasting and conjurations. After the pipe, which precedes all important councils, the medicine men sat down opposite to each other, a few feet apart. The trial of power seems to have been conducted on principles of animal magnetism, and lasted a long while without decided advantage on either side, until the Black Snake, concentrating all his power, or 'gathering his medicine,' in a loud voice commanded his opponent to die. The unfortunate conjurer succumbed, and in a few minutes 'his spirit,' as my informant said, 'went beyond the Sand Buttes.'"

Such stories as this require much better verification than Mr. Browne seems to have obtained, but the occurrence alleged is not impossible.

The so-called medicine bag of the North American Indians is essentially the same in character and purpose as the charms, amulets and talismans of Oriental

nations, and its proper title is "the mystery sac or bag."

The medicine of other uncivilized races is essentially the same as that of which I have been speaking. In Australia the "bilbos," or doctors, endeavor to produce a proper respect and impression in the minds of their patients by the use of a number of slender rods, from six to nine feet long, which are stuck in the ground in the form of a crescent, and are addressed with speeches and gestures. Blood-letting is used, the flowing blood not being wasted, but rubbed on the body of the doctor, in the belief that both parties are thus strengthened. Women, however, are never bled nor allowed to have the blood of other parties placed on them. To cure the headache a string is tied around the head of the patient, and the operator, who is always a woman, takes an end of the cord between her lips and frets them with it until they bleed freely. The disease is supposed to be attracted by the blood, and to pass along the cord to reach it. Suction for local pain is much employed, the end of the performance usually being the production of a piece of bone, which is exhibited as the concentrated essence of the pain. The same practice is found among the Guayacura tribe in Brazil, and in each case the saliva is carefully buried. In the Tonga Islands, and in Patagonia, and among all the South American tribes, the medicine men are the priests who take charge of all difficult cases; but I need not weary you with details. Precisely the same state of things is found in Africa, and very graphic and amusing accounts of the ceremonies used to drive the devil out of the sick man will be found in most of the works of African travellers. Drum-beating, chants and charms are the means used to induce his satanic majesty to depart.

It is also worthy of note that among savage nations we meet with peculiar diseases in which only equally peculiar medication is of service. For instance, the Cossack women are sometimes affected with what is known as the anadyski bol or sickness, in which they are in a sort of trance, speaking unknown tongues, and fall into convulsions if certain articles are not brought to them.⁷

Still more remarkable is the tigaretie disease of Abyssinia, which, commencing with fever, reduces the patients to skeletons, and is often fatal, and can only be cured by music and dancing, being in many respects analogous to the so-called tarantism of southern Europe, or the famous dancing mania which broke out in the fourteenth century. Although such diseases are usually found only among barbarous and ignorant people, they may appear in civilized countries in the form of epidemic chorea or convulsions, often connected with religious ceremonies, as in the convulsionists of St. Medard, the leaping ague of Scotland, or the jerks of the Methodists in Kentucky and Tennessee some years ago, and also, in exceptional cases, without any religious connection. In all such cases magical medicine is of peculiar efficacy.

The very general use of suction as a remedy among savage tribes, not only in this country, but in Africa and the South Sea Islands, is curious and not easy to explain. It may possibly be connected with the animal instinct of licking a wound, which, in the child, is shown by the carrying the injured finger to the mouth, and which, according to Charles Lamb, led to the discovery of the pleasures of roast pig.

The Shamans and wizards of savage tribes, while admitting to the initiated that they make use of sleight-of-hand to impress their patients, have, nevertheless, a belief in their supernatural powers. The ceremonies of initiation into the Confraternity are such as to powerfully stimulate the brain, and a hypnotic or mesmeric state seems often to be produced by them. They also produce hypnotic phenomena in some of their patients, and, in this way, produce effects which, to those not familiar with such phenomena, may seem good evidence of the possession of supernatural power.

It is by no means necessary to cross the ocean or to go west of the Mississippi to find specimens of Shamanism, or of spiritual medication. In the South, you may even yet find a few Obeah men or witch-women who are resorted to by some of the colored population. And here, as in all countries, you can find plenty of what is known as folk medicine, which, as Mr. Black says, contains "the unwritten record of the beginning of the practice of medicine and surgery."⁸ He also points out that three explanations of disease and death appear to be prominent among barbarous and ignorant peoples, namely: "(1) The anger of an offended external spirit. (2) The supernatural powers of a human enemy. (3) The displeasure of the dead."

Now, whether, or not, the quaint superstitions and practices which are found in folk-medicine, as among savage races, are to be explained on the theory that they are fragmentary relics of survival of what was once a complete system of philosophy, or of ancient superstitions and fears, it is very certain that the use of ceremonies, charms, and incantations characterizes, also, the ancient medicine of all nations of which we have records.

As the fundamental principle on which it depends — namely, unreasoning belief — exists in the majority of human beings, it is not strange that it exists in various forms at the present day in all countries, even in the most civilized. Very possibly some of this audience, when children, have tried some charm against warts; and the faith-cure, the consultation of mediums for medical advice, and the effort to ward off death by prayer, either public or private, all of which depend on faith in what we may call supernatural beings and forces, are not uncommon among you.

There is also abundant evidence that any of these methods sometimes have had, and do have, the desired effect, at least, for a time. There are two different ways of viewing such phenomena, corresponding to the two great classes of human minds to which I referred a few moments ago. The first is to assume the existence of beings and forces, or of a particular form of matter which are not ordinarily cognizable by the senses, nor subject to ordinary methods of investigation. This is the doctrine of magic and its derivatives, of which I shall speak hereafter. The other way is to consider how far the results of magic, faith, etc., can be accounted for by what we now know of the mechanism and functions of the human body, and especially of the nervous system.

(To be continued.)

Address.

PERSONAL REMINISCENCES.¹

BY BENJAMIN EDDY COTTING, M.D., ETC.

For some time before and nearly up to my day the art of medicine had been in a rather quiescent state. Diseases had been classified and named; and tolerably well defined methods of treatment had become authorized. There was, indeed, an ever-recurring similarity in these methods for the several diseases. If polypharmacy prevailed, it was polypharmacy according to rule. Given a disease, "a course to steer by" was pretty well laid out. No sick man ever escaped it. Nor, for that matter, did the well fare much better, if they wished to have health assured to them. Venesection, and other prophylactics, were resorted to as the several seasons came around. But the taking of "spring medicines" was thought obligatory on all. Draughts, emetics, and cathartics, were apportioned out to adults with a free hand. Sulphur, with cream of tartar and molasses, was periodically administered to the young; while a new-born infant was not considered fully prepared for life's journey until its stomach had been filled and emptied by a potation of molasses diluted with the vesical secretion of the first youngster that could be secured for the purpose.

Then, too, a doctor's call meant something. An emetic-cathartic inevitably followed the first visit, no matter what the disease might be. No wonder the coming of a doctor was dreaded in those days. But the practitioner then had one advantage—his course was plain. He was called to *do something at once*, and he generally did it. If after that he could only be sure of his nomenclature, his subsequent action was equally simple and marked out for him. "Tell me the name of my patient's disease," said a young doctor who had just then pitched his tent near mine, "and I shall readily know what to prescribe for him!" In all this the practitioner's course was simple and easy. He had to be "heroic" only, with the lancet and heavy doses, and his responsibility was cancelled. If successful, he had been lucky in hitting upon the right medicine; if unsuccessful, it was the patient's misfortune, the fault of the stars, perhaps, but not of the remedies, so-called, nor of the attendant if his treatment had been sufficiently tumultuous. But, alas, for the cautious or unheroic practitioner. His failures were accounted no better than homicides, if not indictable.

But medicine was not wholly at a standstill when I began its study. New investigations, new methods, and new doctrines were enlivening its followers. Auscultation told a new story of the chest to those who had ears to hear. Peyer's patches had begun to show themselves. The numerical method was in full discussion. Louis and his followers were loudly proclaiming the results of his observations. With some, observations were everything; to number their details the chief object and end of science.

But the greatest demonstration of the day, one destined to revolutionize ideas in the treatment of disease the world over, and for all time, was then promulgated to the startled profession. That a fever sometimes would have its run was generally admitted, but

that self-limitation is the rule in most, if not all diseases, was a doctrine the profession was not prepared for.

For what reason I know not, possibly a "philosophical tendency" sometimes attributed to me, I hope truly, I inclined at once to the new doctrines, and even went a little further. Young in medicine as I was, I ventured to ask if disease be self-limited and medicines will not arrest it, why dose it at all,² except to make the patient more comfortable, and if possible diminish his risks. I sought, therefore, for opportunities to observe disease, undisturbed by medication. Fortune favored me.

One of my companions³ was a student, who, previous to taking up medicine, had resided a long time in Germany for other studies, and was a thorough German scholar. Coming home, he had brought with him as curiosities, original publications of the author and followers of the "New System," as it was called. This was beginning to tickle the fancies of unstable heads hereabouts, both in and out of the profession. My friend (who had now abandoned his previous occupation and begun the study of medicine), became interested in "the system," and I shared his interest. By his aid we could study its pretensions from first sources. Together we tried its efficacy. Then we tried parallel cases, and we soon found that for every case in which he could show recovery under its methods I could produce one equally successful treated without medicines. We gave "the system" a fair trial, but both of us soon became convinced by our actual experiments that there was literally *nothing* in it—nothing in its dogmas or its therapeutics. Nature was as fully capable, we found, to cure diseases without as with its assistance. It is unnecessary, perhaps, to add that neither of us became a convert.

When afterwards the practitioners of this "system" were asked to leave the Massachusetts Medical Society, I advocated, for the sake of argument, the society's allowing the *practice*, without committal to its doctrine,—the making a trial of its merits in practice as I had myself done, and as the Society had advocated with other new plans or medicines. It would give, I argued, the regular practitioner a number of elegant placeboes. My proposition met with decided, almost furious opposition from men who declared emphatically that *they never* used placeboes, that to use a placebo was a detestable imposition. Yet these men admitted that they used drop-doses of spirits of nitre in typhoid fever! They advocated expulsion, but years afterwards counselled leniency lest "persecution" should "increase the popularity" of such practitioners who had now become active and obnoxious disorganizers.

There can be no greater mistake than to attribute modern mild medication to the partial success of this baseless folly. This last was a reduction of the former to absurdity. If local tradition and gossip of the day at the place of its origin were correct, the "hayseed pellets" were suggested in derision of the ptisins and gum-syrups of eminent French practitioners, and the "system" was devised afterward when its author, to his great astonishment, found that his satire was taken for new science by the sapient public. The "system" now exists in name only, to at-

¹ See Boston Med. and Surg. Journal, July 4, 1872.² The late Joseph H. Dorr, M.D., etc. He was the most accomplished conversationalist I ever met with, excluding professionals.

tract the fanciful and the ill-advised. Its theory and its treatment receive no support from scientific men. Its recipients swallow its pretensions and its pellets with wondrous simplicity, not knowing the import of its name even. When cured under it, nature cures them. Seldom, however, do such patients escape the "regular" doses they so often denounce, even at the hands of their own attendants.

It has been rather amusing, as time has rolled on, to hear my dissent to such doctrines and practice attributed to prejudice due to ignorance of the whole matter, when probably, with my friend, I had tested the subject by rigid experiments more fully than had all its boastful pretenders hereabouts put together.

As for personal experience, during pupilage I took care of unnumbered cases of measles, and scores of patients in scarlet fever without medication; banishing, no easy matter, hot saffron and similar teas, the then usual resort in such cases "to bring out the eruption," and allowing abundance of light, air, and water, then so often denied the sufferers. Many cases of typhoid fever were also entrusted to my management, and many were the undesired compliments I received for skill in medication which had been successful by omission.

Not many years ago there was a severe epidemic of typhoid among the gentry at the west end of London, with numerous cases and many deaths. As the dwellings were faultless in construction, drainage, and water-supply, and, as theorizers must have second causes, the milk-supply was charged with the introduction of the fever. The milk was of the best character, and from faultless farms especially selected for these people. A man had died on one of these farms a short time before, but his disease had not been even suspected to be of a typhoid character. The story fabricated out of this death, ill-founded as it was, seemed to satisfy the demands, but the assumption is said to have cost the companies over sixty thousand dollars, without utility. Nevertheless, milk is still taken by everybody, in England as well as in other countries, and epidemics continue to break out where they cannot be attributed to it, or to any other discoverable cause. Thus epidemics will occur when and where least expected. They have always done so, and probably ever will continue, in spite of the "authorities called upon to suppress them," to the end of time, or until the limit assigned to them in the course of nature.

A most eminent zoologist once gave in detail to an equally eminent mathematician the conditions of existence of a parasite, its manner of reproduction, its rise, its residence in different "hosts," the dangers that beset it throughout existence, etc., etc.—and the mathematician *calculated* that, by the doctrine of chances, the creature could not be reduced to extinction. From this there would seem to be but little probability of our being able to "stamp out" disease by destroying its microscopic or invisible causal or attendant organisms, by means of "germicides," or by a proclamation of the sheriff, while we fail in ability to exterminate a tape-worm or an acarus, or any similar visible monster. Is it not more than probable that disease, like other created things, will leave the world, if ever, as the ancient saurians did, or the dodo in historical times, only in the course of events.

I early had experience in two severe epidemics of typhoid: one during pupilage, and one just after grad-

uation, the latter when acting *locum tenens* while the resident physician of a large village took a vacation. The outbreak began just as my friend was leaving, and continued until sometime after his return. By his books it appeared that the disease had occurred in over seventy houses in our circuit. No cause for it could be assigned. Other neighboring physicians were equally occupied, in their villages, and I was fully acquainted with their treatment. My own methods were generally acknowledged to be at least as good as theirs; and I had not used active or perturbing medicines. Their measures were generally of the more "heroic" kind. I saw one of their patients taken out of a wet sheet, "a cold pack" as it was called,—dead! The fever had been broken up.

In an epidemic of typhus fever, some years later, and among immigrants chiefly, I took care of three hundred and seven cases without administering drugs. Thirty-one died or about one in ten. In the same epidemic and in the same class of people, at Ward's Island (where the commissioners declared in their report that the "practice had been among the most successful,") there were two thousand and nine cases, with four hundred and twenty-seven deaths, or more than one in five. This was noticed by officials nearer home, who publicly reported, in print, of my cases that "it was apparent that the mode of treatment must have been judicious and skillful from the small number of deaths which occurred."

Moreover, in this epidemic, another point was noticed; some of the attendants were attacked. Of these, where the onset was of the severest character, even to delirium, there were instances of rapid abatement and of convalescence in a few days, the disease having been "broken up" by non-interference.

Before I came to Roxbury I had practised venesection so often for other physicians that its performance was to me an insignificant matter, yet so thoroughly had I become convinced of its uselessness, or harm, that I did not bleed in the first case of pneumonia, here coming under my care. The patient was a man of standing and influence. I suffered much anxiety during his illness, for I well knew that if he died I should be unsparingly denounced by practitioners and laity, and perhaps be obliged to leave the place. Still I resolutely did as I would be done by. The man recovered, with less damage apparently than is usual in such cases. I have never bled in that disease since. Moreover, the influence of this case, with other similar cases, was surprisingly marked on the general practice of the neighborhood. Practitioners hereabouts soon began to learn that milder measures and less disagreeable doses, matters which I often advocated at our Medical Meetings, are quite as effective for good, and deprive the sick-room of much of its discomfort and dread.

About the time of my pupilage, surgery was thought to have reached a pretty high degree of perfection. Some of its ablest men had gone but many remained. I do not call to mind any startling innovation or radical change. The subcutaneous division of tendons was for a while much talked of, but a "run" in that direction did not promise a great deal, for as one of its principal performers, who really seemed to have foundation for his remark, said in my hearing, that he did "not see why, in God's name, all deformities occurred among poor people."

The great revolution in surgery came not long

after, on the *accidental* discovery of anaesthesia. I call this an accidental discovery, though in fact it was rather the accident of an accident. An adventurous dentist happened to have a nervous patient, who wished a tooth extracted, but failed in courage at the critical moment. The dentist, out of patience, sought for something to engage her attention while he could seize the tooth. He applied to a well-known chemist for a gas-apparatus to serve as a *ruse*. The latter, as the dentist was leaving, called out in an nonchalant manner, "why not try ether, that'll put her to sleep." This was more than the dentist asked for, and there is no evidence that *at the time* either of them was contemplating a *painless* operation. That point was not in question. Control of the patient was the only object then sought for. With his forceps on the tooth the dentist would finish the operation, no matter how *painful* it might be.

Now sulphuric ether was then well known to chemists, and taught by them, to be capable of producing "a degree of intoxication when its vapor was inhaled by the nostrils," but taught always with the caution that "this may prove dangerous or even fatal." Our chemical teachers, this very chemist among the rest, had annually told us all this, for I quote their very words. How much the dentist knew of ether is uncertain, nor is it material, but, heedless of consequences, he at once obtained some, tried it upon himself, and *sleep* a while, unharmed. Thus far a chance-word had had its effect. Had the dentist known as much as the chemist was supposed to know, perhaps he also would have thought such experiments, as his own upon himself, too "reckless," as the chemist called them, and the discovery would not have then been made by him.

Again, a fortuitous occurrence, the turning point in the whole matter. By good luck the dentist's next patient happened to be one (and we have since known not a few such) to "go off" without a struggle on the very first inhalation. This was a lucky chance indeed, for had it been otherwise, the whole thing would have failed. The agent was administered. In a moment the patient, to the untrained eyes of the operators, seemed to be expiring, apparently *in articulo mortis*. The dentist, startled but not demoralized, immediately extracted the tooth, to have something to show for his venture. The patient, reviving as quickly as he had succumbed, declared that he "knew nothing of the operation and had *not suffered pain*." The astonished dentist, controlling his emotions, at once obtained an attested written document to that effect; and immediately sought to have his discovery confirmed by others whose authority would not be questioned. Thus a succession of chances produced a glorious result.

These facts, and they are the *facts*, should not detract from the honor due him who so quickly seized upon the offered boon, had it thoroughly tested, and made it available to the world. Therein was the merit, and the whole of this was his and his only; and he should have the credit of it.

All these things I was personally cognizant of at the time. Most of the parties except the dentist, who was previously unknown to me, were among my intimate friends or relatives; and while I dwelt near enough to know all the facts in the matter, I was fortunately far enough away to escape being involved in the controversies. I knew the chemist long and well, and I am as sure of it as of my own existence, that

without the dentist, or one like him, this discovery would not then have been made. When asserting his claims before a body of scientists, the chemist was asked by an eminent savant (who had just come among us, and happened to be present) "doctor, did you make one *leetel experi-ment*?" The chemist hesitated; but on a repetition of the question was obliged to confess that he did *not*. "I think it would have been better, doctor, had you made one *leetel experi-ment*." Therein was the gist of the whole matter!

That one who had never made an experiment in that direction, and who at first had, with an emphasis and rightly, disclaimed all connection with it, and had denounced it as "a — humbug," should have, so soon after its success was known, claimed the merit of the *whole thing*, is sufficiently surprising; but that a demagogic foreign practitioner, who had subsequently merely made use of a kindred agent, a deadly one at that, *brought to him by another person*, should have had the effrontery to appropriate to himself the whole credit of obtaining true anaesthesia, and to accept civic and other honors in return for such meritorious achievement, is almost passing belief. A well-deserved and withering castigation at the hands of the ablest of Boston physicians almost took the life out of the victim, and made the friends of the trickster writhe. They should now cease to worry his manes with undeserved revulsion.

Of the great revolution in surgery effected by anaesthesia, there is no need of mention here. It has not only enabled the performance of many and formerly impossible operations, with ease and safety, but has wholly altered the manner of operating. Sometimes an old operator becomes impatient at the slowness of the procedure, and longs to take the knife and finish it with a stroke.

The first experiments in this country with chloroform were made at my house, by the chemist above spoken of, who had received the article from Edinburgh, only a few hours before. He, himself, administered it to several then present, one of whom experienced alarming symptoms. In the present knowledge of its deadly character, the wonder now is that a fatal result was averted.

There has been another, milder, and more recent sensation which has not wholly subsided. I refer to Listerism. That there was need enough in some foreign hospitals, possibly in our own though I cannot think it, for a cleaner management of wounds and wounded persons, and for less objectionable dressings, no one need be told who had visited them in days gone by. But the opposite extreme does not seem to have been called for; accordingly, much of the original trumpery and complicated processes of the new scheme have been abated. Less cumbersome dressings have been adopted. The foul smelling agents that were first considered essential have, it is said, been abandoned by their originator, as harmful or even dangerous, while it is sought to sustain the "principle" by other more agreeable and less pernicious substitutes.

If, as of old, simplicity of dressings, cleanliness, proper chance for exit of secretions or accumulations, (and it is difficult to understand even now, why the thread of a "long suture" so much inveigled against, soft and flexible as it is in the moisture around it, is not as good a conductor for drainage as a tube many times larger, and liable to become rough by erosion, etc., and, where there are no long sutures, a depend-

ent point left uncompressed will ordinarily answer all needed purposes)—if these things, with rest and support of the parts involved, are thoroughly attended to, there will be less need of the harmful measures and agents even now advocated, whatever may be the accepted theory of absorption or infection. A few years ago the true principles and methods in the care of wounds were well set forth by one of our members before the Massachusetts Medical Society, in a paper which the late Surgeon George A. Otis, United States Army, compiler of the "Medical Memoirs of the Civil War," highly approved of and supplemented.⁴

It has been said that every surgical aspirant must invent a splint. Without ever having been such an aspirant, but having "a mechanical turn of mind," I have used half a dozen or more, constructed by myself, or adapted for simplicity or availability. Accounts of some of these I published; mention, however, should be made of the great value of splints constructed of pasteboard, or thick paper strengthened by strips of iron,⁵ a suggestion of the late Dr. Ira Allen, a much lamented member of this Society. They are easily made, are very firm, and exceedingly light, so light that the patient hardly recognizes their application. I have made and used dozens of them. They are susceptible of any kind of shape or twist, being admirably adapted, for instance, to fractures of the elbow, of the patella, Colles's, and even to fractures of the neck of the thigh bone—enabling the patient to sit up, to be moved about easily, with freedom from most of the usual restraints enjoined in such injuries.

When I began bandaging was a complicated and cumbersome matter, difficult for the attendant and a burden to the patient. For example, the regulation bandage for fractured clavicle required three rollers of nine yards each and a large axilla pad, the application of which was a severe test of a student's adroitness and proficiency in the art of bandaging. I tried many schemes to get rid of some of this, and to find simpler and equally effective methods. Naturally, I was pleased with the handkerchief bandages of Dr. Mayor, of Lausanne, of which he had published an account;⁶ and I obtained many useful hints from his very practical suggestions on extemporaneous treatment of accidental and other injuries. His two handkerchief arrangement for fractured clavicle was an immense improvement over the cumbersome affair mentioned above.

I have also altered if not improved a few minor operations, and originated one which seems at length to be finding favor in the profession.⁷ It is founded on a new principle, and promises uniform relief from a very troublesome and disabling affection.

In a pecuniary point of view surgery has not much to recommend it to the general practitioner. Occasionally a large fee is heard of, but the average is small. From the nature of their employments surgical cases occur mostly among laborers and the poor. Personally it helped me in a marked degree in a somewhat peculiar manner. He who dosed largely was considered the bold man, the "heroic" practitioner. No matter how small the dose, I have never been accused of fear to give a larger, or of want of heroism.

My surgical boldness effectually precluded such a charge! . . .

In 1848, I went abroad to see how much better they order these matters in foreign lands. My famine was over. I had repaid to my over-generous parents the cost of my professional education, principal and interest; and had laid up enough to authorize the proposed outlay. . . .

It was a year of revolutions. We were in Paris during many sanguinary *coupees*, and the four days of the great insurrection, seeing enough of fighting, and military surgery. I passed several months in attendance on the services of the noted men of the time, in the hospitals and elsewhere, and then visited some of the principal medical centres, on the Continent and in England. . . .

In 1860, I made a more extended tour, through Spain, and eastward as far as Constantinople and the Black Sea. . . . Desirous of acquiring some little knowledge of people in the ordinary exigencies of life, in their homes as well as in public institutions, in most of the places I visited I sought opportunities to see private patients with some medical resident, and this of course in addition to the ordinary sight-seeing and routine of most travellers. Thus in Rome, after having *done* the city even to a fearful descent into the catacombs, I became the guest of Dr. Valerj, medical professor in the University. Through him a door was opened to things not usually accorded to strangers. He showed me hospital and private patients, and the medical collection of the College. One of the latter was rather unique, representing the fingers of the operator passing into the abdomen through the walls of the gravid organ at term, in an attempt to dislodge its contents! Through him, too, I was made a corresponding member of "*l'Accademia de' Quiriti*," a prominent Society of all sciences.

When in Rome we had an opportunity to witness a "real miracle." Some thousands had assembled in St. Peters, to assist in the canonization of a saint. Many hundreds of candles had been lighted and the illumination was at the point of completion, when a very long ladder slipped from the hands of the workmen and fell diagonally across the multitude. The impending fall had been noticed in season for the crowd to divide, and to let the ladder come crashing down without striking any one. As soon as the appalling murmur of the terror-stricken mass had somewhat subsided, an official jumped upon a seat and loudly proclaimed that no one had been injured. To the Pope, who came in at this moment, the circumstances were explained and the story of the wonderful escape told, to his apparent great satisfaction. The ceremonies proceeded without further delay. The next evening, as we had predicted, an illuminated broadside appeared attributing the complete safety of the people to a miracle of the new-made saint. Dr. Valerj, however, whispered in my ear that he had that day attended three premature deliveries directly attributable to fright and shock from the accident.

(To be continued.)

— Dr. Fordyce Barker says in the *American Journal of Obstetrics*, that the most valuable remedy for hemorrhages, occurring near or at the climacteric, is a combination of equal parts of fluid extract of hamamelis and fluid extract of hydrastis.

SOME OF THE OBSTETRIC AND LEGAL RELATIONS OF INFANTICIDE.¹

BY F. W. DEWEYER, M.D.

Assistant Professor of Legal Medicine in Harvard University.

REGARDED from the obstetric point of view, these cases are chiefly useful for their negative significance. They illustrate the principle that parturition in its normal processes does not involve pathological elements, but is physiological in nature. They hint that meddling midwifery may well be reserved for abnormal conditions only. They show that healthy women are not dependent on the interference of art to guide them through the crisis of child-birth safely and quickly. They tell us that primiparae are not inevitably condemned to suffer hour after hour of tedious labor. They remind us that the dreaded microbes are not always successful in colonizing for mischievous purposes, even when the conditions, mental, moral, physical and hygienic, apparently favor. These women, pregnant out of wedlock; anxious through the whole period of utero gestation to maintain the appearance of virgin elasticity; dreading, too, the outcome of their follies; depressed by the perpetual fear of exposure; carrying their secret burden with constant apprehension of the suspicious eye or the accusing word; ignorant of the true nature of the process of child-birth, yet knowing well that it is something hard to endure; these women were the most proper subjects for puerperal fever to fasten upon and destroy. Yet they were exempt from accident in child-birth and its consequences; the lacerations, hemorrhages, syncope, air-embolism and other baleful disasters which the accoucher remembers and apprehends as among the possible incidents of each new case to which he is summoned, formed no part of the history of these unattended labors. The women gave birth to their children according to nature's plan.

All this is not to be regarded as in any sense an argument against the intelligent practice of the obstetric art. It is not saying that there is no use for the methods and measures which modern midwifery approves. It is not a protest against the admirable demonstration of the utility of antiseptic precautions lately made before this Society. It is not a hint that the attendant in a lying-in room should stand with folded arms till the first cry of the extruded child warns him that he may now proceed to cut and tie the funis as his primary overt act in a normal labor. To use these cases in such a way, does not enter into the writer's purpose. The lesson which they teach is of another sort, and one which every obstetrician's experience amply illustrates, namely, that normal midwifery does not require meddling interference and that the highest art consists in the prompt recognition and skillful management of abnormal obstacles to parturition.

In one other respect these cases are of some interest to the obstetrician. They show the extraordinary endurance which healthy women may exhibit. If the constraint of secrecy were removed from these patients, if the fear of discovery were not an ever-present and controlling force in their conduct, they undoubtedly would have presented all the emotional manifestations to which obstetricians are accustomed

in the lying-in room. But held in check by a firm purpose to conceal their sexual imprudence and its consequences, they suffered their pains in secret, making no outcry; dreading, instead of welcoming the approach of help and sympathy and after all was over, stoically assuming the appearance of an ability to do their usual daily tasks. For such fortitude, though misdirected, they deserve to be mentioned with their dark-skinned sisters of the Indian tribes, who disdain to delay the migratory march of their people, for such a commonplace event as a lying-in; but the child being born, it is put at once upon its travels, with the puerperal mother, as if nothing had happened.

There are other obstetric relations which these cases suggest and which would well repay examination. Affairs of infanticide frequently give rise to such questions as these:

To what extent do artificial respiration, inflation of the lungs and other measures of the accoucher for the resuscitation of the apparently asphyxiated newborn child interfere with the value and reliability of the hydrostatic test and other proofs of respiration?

Is it probable that a woman in labor would be able to do fatal violence to her child in attempts innocently made by her to aid her delivery?

Is it probable that a woman, more especially a primipara, mistaking labor-pains for colic or a call to defecate, can have such a precipitate parturition while seated in a privy, or a water-closet, that her child is dropped from her and destroyed in a perfectly unavoidable and excusable manner?

May women be delivered unexpectedly while in the standing posture in such a manner that the child, rupturing the funis in its fall, can come upon the floor with such force as to produce injuries to the head, fatal in character and easily mistaken for those produced intentionally?

Is it probable that the navel-cord encircling the neck of the child, within the womb and during the birth, would produce marks upon the skin and other anatomical appearances readily interpreted as due to violent strangulation with a ligature?

May spasmodic contraction of the os uteri around the neck or other part of the child's body during the birth, cause the child's death with resulting appearances closely simulating those of violence?

But in addition to their value as obstetric anomalies these affairs of infanticide have an interest of another kind. Medico-legally they offer many attractive topics for discussion. Perhaps the most important of these is the fact that they are almost invariably barren of results when they become the subjects of judicial investigation. It is one of the rarest events that a woman accused of killing her new-born child is convicted and punished, or even brought before a jury for trial under an indictment. In ten years of service as a medical examiner, the writer has never been called upon to testify at a jury-trial in a case of this class, although he has reported to the authorities a very considerable number of instances in which the anatomical appearances left no reasonable doubt of the violent manner of the child's death under circumstances that pointed directly to the mother as the agent. The testimony of other medical examiners in Massachusetts shows that this experience is not singular, but that prosecutions in this variety of crimes are remarkably few.

The explanation of this state of things is not far to

¹Read before the Obstetrical Society of Boston, November 12, 1887. Concluded from page 11.

seek. That unmarried women may kill their illegitimate offspring with such impunity, is a fact that rests on legal grounds, and not on want of medical evidence. The anatomical proofs in these cases are not wanting in clearness and directness. The medical investigation of an affair of infanticide, while it involves some special elements insisted on by legal traditions, is not, in general, a difficult undertaking. Whatever the cause and manner of the death, the child's body will disclose the evidences of it as plainly and decisively as would the body of an adult. Asphyxia in its various forms, wounds, poisons—all the methods which unlawful violence uses to destroy life are as demonstrable upon post-mortem examination in the case of the infant as in that of the man.

But the medical investigation is not ended at this point. The moment the examiner enters upon the work of clearing up the medical problems involved in an affair of child-murder, he is met at the very threshold by a series of questions which the law asks and to which it requires an answer. The first of these questions is: "Was this child born alive?" And the medical examiner seeks for anatomical evidence that will enable him to answer in the affirmative. He observes the organs of respiration with particular care; he notes the position, volume and color of the lungs; he looks for the boundary-lines of the pulmonary lobules and for expanded air-vesicles: he feels of the lungs to determine if they crepitate under pressure; he places them in water and while they are submerged he cuts them, noting if they emit bubbles of air from the section; he tests their buoyancy in water, carrying his test from the organs in their entirety to minute sections of lung-tissue forcibly compressed; he explores the trachea and bronchi for air bubbles; he examines the stomach to ascertain how far air has become intimately mingled with the gastric mucus or with blood swallowed in the course of the birth; he notices to what extent the small intestine is inflated with air; he searches the kidneys for the yellow lines of uric acid infarction; if he is inclined to exhaustive over-refinement in his researches, he explores the cavity of the tympanum to learn if the middle ear has lost its so-called "mucus mass" of intra-uterine life by the introduction of air. And if his observations are satisfactory to him, he replies: "Air has entered this child's body, expanding the lungs, leaving its presence manifest in the stomach and the intestines and ventilating the middle ear through the Eustachian tube. It is my belief that the child was born alive, and that the changes found as described were due to the natural acts of respiration and deglutition."

But the law requires something more than this: it not only assumes for purposes of evidence that the child was still born, thus throwing upon the prosecution the burden of proving the contrary, but it also declares that "with respect to the birth, the being born must mean that the whole body must be brought into the world,"² and it asks the medical witness if

his examination enables him to state whether the child was "wholly" born at the moment of its death. To this extraordinary question, the reply is necessarily in the negative; for so far as the post-mortem appearances are a guide, one cannot state that the foot, the leg, the pelvis, the entire trunk, in short, the whole body of the child, save the head, was not in the maternal passages when the act of respiration began and wrought the changes observed in the lungs. Indeed, many well-authenticated instances of the *vagitus caginalis* and the *vagitus uterinus* constrain the medical expert to admit that the changes noted in the lungs and digestive tract may have occurred, under favoring conditions, even while the child was wholly unborn, instead of wholly born, and while the entire body was within the womb; but he insists on qualifying this admission lest it prove too much, and he explains that such a remarkable phenomenon as the audible cry of a child within the mother's womb requires the entrance of air to the fetal larynx, and this cannot occur except with the face presenting (an abnormality predicated a tedious labor and the assistance of an accoucheur) and except, also, with the vaginal canal patulous through the manual interference of a witness of the birth.³

But the law gives the defendant mother still another chance of escape; it requires proof, not only that the child was living when it was born, and that it was wholly born when it died, and that its death resulted from the violence as charged, but it goes a step farther and asks for evidence that it had an "independent existence" when it died from the violence.⁴ At this point, the medical witness realizes fully the limitations of his science when applied to the needs of the criminal law, and is forced to admit that all his carefully conducted observations and tests have little value as controlling evidence, when the violent death of a new-born infant "*infans sanguinolentus cruciatus*" as the Roman law describes it, is the subject of inquiry; and that his proofs are useful only so far as they corroborate the testimony of an eye-witness of all the details of the birth and death, who can aver that the child did not breathe and cry and suffer violence and die before every part of its body was fully born, and before the blood ceased to flow from the mother to

² A case recently tried in a German court shows that continental jurists attach a rational view to this question here described, with reference to the relation which a *foetus* bears to infanticide; although it is difficult to understand how the very narrow line which the German law lays down can be demonstrated by any testimony save that of eye-witnesses. A practitioner was called to attend a woman in her confinement. The presentation was a shoulder one, with an arm prolapsed. After an ineffectual attempt to turn, the arm was cut off; then followed another unsuccessful attempt to turn, after which the other arm was amputated and the lower jaw was torn out. His attempts to deliver were still fruitless, and another physician was called in who delivered the woman. The first practitioner was cited before the court and the experts unanimously declared that the child had been killed by the injuries inflicted on it, and that the defendant's theory that the child was already dead when he dismembered it was not true. Death by negligence having been proved, the defendant set up the claim that it was not a homicide, but negligence under the German code, for the *foetus* up to the time of dividing the cord, was a part of the mother's body, and the case was only a negligent wounding of the mother. The court ruled that the Strageschloech recognized the vital existence of the *foetus* and protected it as a human being as soon as a part of the child became visible outside the vagina, and declared the killing of a child in or immediately after birth, as the killing of a human being, or homicide. The court, therefore, held the accused guilty of homicide by negligence, and condemned him to several years' imprisonment. An appeal was not allowed. Münchener Medizinische Wochenschrift, Medical Press, June 22, 1887.

³ Rosen, *op. cit.*, p. 269. See also *Groundwork on the Law of Evidence*, III, p. 129, (4th Ed., 1876); and Archbold (*loc. cit.*) p. 596, quotes Mr. Justice Parke as ruling in a case of alleged child-murder by stabbing with a fork: "The child might breathe while wholly born, but its having breathed is not sufficiently life to make the killing of the child murder; there must have been an independent circulation in the child, or the child cannot be considered as alive for this purpose."

² Rosen's Digest of the Law of Evidence in Criminal Cases, Eighth Ed., 1874, p. 799.

Archbold cites this case: "Where the prisoner was indicted for the murder of her child by cutting off its head, and a surgeon stated that he was enabled to say definitely that the child had breathed, but he could not swear that the whole body of the child was born when the act of breathing took place, Colman, J., said: 'In order to justify a conviction for murder, you must be satisfied that the entire child was actually born into the world in a living state. The fact of its having breathed is not a decisive proof that it was born alive; it may have breathed yet died before birth.' Rex vs. Sillis, 7 C. & P. 890." Archbold on the Practice, Pleading and Evidence in Criminal Cases, Seventh Edition, 1870, I, p. 826.

the child, through the umbilical vein. Such a fortunate conjunction of ordinary and expert testimony cannot be a common occurrence!

And so the twenty-three men who constitute the grand jury, having sworn to "present things truly, as they come to their knowledge, according to the best of their understanding," apply their "average intelligence" to the curious problem before them and inquire if the mother's guilt is probable, and therefore indictable. They learn that the case is one in which the evidence is wholly circumstantial; no one saw the young woman destroy her illegitimate child, or do any violence to it; no one assisted her in her labor; no one can testify, as a matter of fact, as to the condition of the child at its birth, or the manner in which its death occurred; it is purely a matter of medical opinion. Then another influence, that of pity, comes to the defence of the woman. These grand jurors are not without some sense of chivalry and sympathy, and they say among themselves that it is contemptible to pursue this woman, more sinned against than sinning, betrayed and deserted by her lover, left to meet her shame and all its consequences single-handed and alone, suffering the dreadful pains of childbirth in solitary and silent misery, perhaps irresponsibly unbalanced when her child's first cries announced to her the culmination of her woe;—it is a cruel wrong to follow further with the strong force of the law a weak woman, already amply punished by physical and mental pain. And then the child is better dead; it was an illegitimate offspring; it would have grown up disowned and dishonored, a bastard and probably a perpetual charge upon the State's charity. And the natural and usual result of it all is, that in cases of infanticide, where direct, positive evidence of the facts relating to the child's birth and death is wanting, the grand jury votes not to indict. The admission of the medical witness that he finds it impossible in such cases to meet the requirements of common law precedents as applied to infanticide, is an element of importance in this result. But if, perchance, an unsympathetic grand jury should send an indictment into court for trial, with nothing but medical opinion as its foundation, one can well understand how competent counsel for the defence would use the rulings of the highest English courts for his client's benefit.

Now if the killing of a new-born illegitimate child in the secret solitude of the lying-in room be really a crime worthy of punishment, rather than a mischance to be excused, and if it be desirable to enforce measures to prevent such felonies, it is not impertinent to inquire if criminal jurisprudence is right in creating and perpetuating precedents which will be for the guilty mother a mighty ally in her time of trial, and which if they do not actually encourage child-murder, certainly do not help in its repression. Under the established rules of civil and of ecclesiastical law, the unborn child has well recognized and undisputed rights; its independent personality is admitted; it may through its mother claim damages, it may have money or estates left it by will, a guardian may be selected for it or it may be appointed an executor.⁶ But the common law relating to crime regards the matter differently; "a child in the womb is considered *pauis viscerum matris* and not possessing an individual existence, and cannot therefore, be the subject

of murder."⁶ It follows very naturally and properly, therefore, that "to support an indictment for infanticide at common law, it must be clearly proved that the child was wholly born and born alive, having an independent circulation and existence."⁷ Can there be any doubt of the inconsistency which exists between this judicial position and the dictates of sound ethics, enlightened reason and progressive science? Such a view of the legal relation of the unborn child places property considerations higher than the saving of human life; it permits the unborn child to set up and establish claims to estates, but declares that the right to its existence as an independent being and the right to have that existence protected by law cannot be recognized; it ignores the fact that the intent to kill is the same at whatever age of fetal or of infant life the assault is made; it offers encouragement to the abortionist by assuring him that it is not a crime to destroy a fetus, and it narcotizes the conscience of the accomplice mother, who aids and abets the abortionist in his act of murder.⁸

But suppose the law relating to the evidence of crimes should adopt the ground accepted by the civil law with reference to the unborn child; suppose it should declare, either by statutory enactment or by the rulings of judges, able and disposed to break asunder the bonds of tradition and of ancient precedent, that it recognizes in the product of conception, in the viable fetus especially, a human life entitled to full protection; that it will assume for purposes of evidence that, though hidden in the mother's womb, the child is living and that the intent to destroy it is a criminal intent; that proof of its destruction, whether within the womb or in its transit therefrom or after all anatomical connection with the mother has been severed, shall be subject to the rules of evidence which control all indictments for murder or manslaughter, can any one successfully maintain that harm would result in any direction? If the criminal law would but hold that the words "Thou shalt not kill!" are sufficiently inclusive to cover the unborn and the new-born child alike, we should hear less about insuperable difficulties in the way of medical evidence; unchaste women would soon learn that the killing of their bastard offspring was a crime to which a punishment was attached; abortionists and their guilty patrons would feel that they must find new safeguards against detection; and even obstetricians might find it profitable to reconstruct their notions of legal and moral responsibility before undertaking lightly the induction of premature labor or the use of the cranioclast.

—The late Mme. Boucault, of Paris, at the time of her death manager of the "Bon Marché," left, among several millions to public charities, 10,000,000 francs to the "assistance publique" for another hospital.

⁶ Bescoe, loc. cit., page 708.

⁷ Greenblatt's Law of Evidence, 111, page 120.

⁸ The writer is aware that with reference to criminal abortion, so-called, the law does regard the intent of the accused as the essential point in issue and it does not require proof, therefore, that the womb of the woman operated on contained a living fetus, or a normally formed fetus or indeed any fetus at all, at the time of the operation. And this very fact, that the existence of the fetus is ignored altogether, and that the crime is decreed to be against the mother only, for this the position taken in the paper. If the words of the Massachusetts Statute "whoever, with intent to procure miscarriage of a woman" (Pub. Stat. Chap. 207, Sect. 29) were amended to read "whoever, with intent to destroy the life of an unborn child and to cause its premature birth," they would more nearly express the true nature of the crime and the true motive of the feticide.

APPENDICITIS, WITH REPORT OF CASES.¹

BY HERMAN F. VICKERY, M.D.
Assistant in Clinical Medicine, Harvard University, Physician to Out-patients, Massachusetts General Hospital.

In an exhaustive paper read before the Association of American Physicians, by Prof. R. H. Fitz, and published in the *American Journal of the Medical Sciences*, for October 1886, it is stated that in a majority of the fatal cases of the disease variously known as typhilitis, typhlo-enteritis or perityphlitis, the essential pathological element is an ulcerated and perforated vermiform appendix. Adopting this view, I have applied the proposed name of appendicitis to the cases now reported. I venture to premise a brief description of the disease, chiefly in order to furnish a basis for discussion.

Appendicitis attacks four times as many males as females, and three-fourths of its victims are under thirty years of age. In children, and exceptionally in adults, prodromata may last for days or even months, consisting of anorexia, vomiting, irregularity of the bowels, more or less pain, felt chiefly in the right inguinal region, and a local swelling. The attack is usually sudden. There is a violent pain in the right groin, perhaps associated with a chill or with collapse. There may be no fever, but usually the temperature ranges from 100° to 102° F. Frequently there are vomiting and hiccough. Constipation is to be expected; but we may see diarrhoea or dysentery. It would not seem unnatural that the lower portion of the bowels should empty themselves in the early part of the attack. If, however, later on in the disease, there should be copious dejections, it would suggest that the cæcum proper had thus far escaped. From its incipency, appendicitis is accompanied by localized tenderness; and by the third day we may expect more or less dullness on percussion and a sense of resistance. If external examination prove negative in its results, digital exploration of the rectum should never be omitted.

When these signs of inflammatory exudation are found, it is usually advised to insert an aspirating needle, in order to determine whether pus is present. In view of the frequent failures to find pus, when it exists, by this means, I believe that laparotomy should be immediately performed, provided the eliminative diagnosis has been a careful one. Faecal accumulations in the cæcum tend to form a more elongated, vertical, nodular tumor, perhaps accompanied by a similar distention of the transverse colon, and seldom associated with fever or with so marked signs of local inflammation. In women, pelvic troubles must be considered, and a vaginal examination made. Hematoecle has been mistaken for appendicitis and *vice versa*. Internal as well as external hernia should not be forgotten, nor in children the possibility of intussusception.

The reasons for the early removal of the pus are: that the usual cause of death from appendicitis is the development of a general peritonitis; that this peritonitis occurs in more than half the fatal cases before the fifth day; that it is in most instances due to an escape of pus into the general cavity; and finally, even if the abscess remains localized, there is a longer illness and greater danger involved in expectant than in modern operative treatment.

The earliest treatment of the case can be described

as an effort to limit the suppurative inflammation to its original seat. The patient must therefore maintain absolute physical quiet, have the most simple liquid food in small amounts, and not merely his pain but the peristaltic action of his bowels must be subdued by opium pushed to incipient narcotism. Poultices, or if these be too heavy, hot compresses will also be grateful to the patient and contribute somewhat towards the desired end.

Alonzo Clark believed "that a large proportion of the cases of peritonitis in children are due to perforation of the appendix." It may be that even in those instances where appendicitis and a general peritonitis begin almost simultaneously, prompt operative measures will save life.

Within the last two years the following cases have been seen by me in private practice.

CASE I. The patient was an overworked clergyman and author, aged fifty-four, who had long been subject to constipation, which he overcame by mineral waters and fruits, especially figs. He was feeling more than usually fatigued when the attack, about to be described, came on. One Sunday being away from home to preach and having had an indigestible breakfast, he began to experience abdominal pain during the morning service. He finished the exercises, and then sent for a physician; who regarded the attack as one of simple indigestion, but was obliged to give morphine subcutaneously to relieve the pain. The next day, feeling better, the patient was permitted to ride nineteen miles in the cars, back to Boston. That afternoon I saw him. He was in bed, pale, and with cool extremities. The temperature was 102° F., the pulse 108, the respiration 20. The abdomen was tympanitic, but not tender. I saw no reason to doubt the diagnosis already made, ascribing his debility to the imprudent journey. The symptoms of his illness were nausea, vomiting, constipation and tympanites, but for the first five days there seemed to be a slow improvement. The little pain there was referred to the left side of the abdomen. Tenderness was slight. There was at no time dullness or increased resistance in the right iliac region. No rectal examination was made, an omission to be regretted, but as shown by the sequel, probably of little importance in this particular case. Dr. Sheldon, of Wakefield, saw the patient twice with me. Trouble in the caecal region was considered, but the evidence of its existence seemed wanting. Up to the sixth day, there had been improvement, if anything, in the general condition. Upon the morning of the sixth day, however, it was found that a marked change had taken place. There was decided collapse, but associated with it a painful restlessness. The tympanites was extreme, although even now there was little tenderness or pain. The face was pinched. The occasional vomiting had given place to the peculiar, persistent and easy vomiting of peritonitis, resembling regurgitation.

Dr. E. N. Whittier was called in consultation, and confirmed all our fears as to diagnosis and prognosis. Early on the morning of the seventh day, death occurred. The autopsy was made on the next day by Drs. Trull, Emerson and Titcomb, of Concord. Dr. Sheldon was also present, and he states that there was slight objective evidence of general peritonitis. There was typhilitis, but no perityphlitic abscess. Through a minute perforation in the appendix, pus could be pressed into the abdominal cavity, in which

¹Read before the Boston Society for Medical Observation, November 7, 1887.

were found two minute bodies, one of them resembling a fig-seed, when it was put under a lens. Death was ascribed to the shock caused by the perforation.

CASE II. Mr. A. H., aged twenty-seven, clerk, had a grandmother who died of "stoppage of the bowels," and his brother is subject to digestive disturbances similar to those which for the past five years have affected our patient. The attack begins with epigastric pain, sometimes shooting down the right side, which is constant, but which has exacerbations. Nausea and persistent vomiting soon come on. The attack lasts about a day, and then the patient feels well until the next one begins. The bowels are usually regular. These attacks have gradually increased in number and severity. Two occurred within a month of the illness in which I first saw him. A third attack began January 4, 1886, in the afternoon and lasted all night. He took some laxative pills, on general principles, not because of constipation, and somewhere about noon he had several operations, which were examined and not found to be peculiar in any way. Not long after, while lying quietly in bed, he was suddenly taken with most excruciating pain in the right iliac region, which increased rather than diminished in severity. When seen by me about an hour and a half later his face was pinched, his extremities were cold, and his pulse small. After two doses of morphine, given hypodermically, he was relieved. Absolute rest in bed was enjoined, hot compresses applied, and pain was kept in abeyance by deodorized tincture of opium. The temperature at no time rose above 100.5° F. There were nausea, hicough, tympanites, constipation and abdominal tenderness, especially in the right iliac region. No dulness nor increased resistance could be made out, however. On the sixth day I felt per anum a slight and tender swelling high up on the right side. This was also felt by Dr. Whittier, whom I now called in consultation. On the following day flatus escaped per anum, and on the next day, the eighth of the attack (reckoning from the violent pain), the bowels moved. On this day Dr. F. B. Harrington examined the patient with me, under ether, and advised an operation, which was immediately proceeded with. Dr. C. W. Townsend and Dr. Whittier were also present. Dr. Harrington made an incision parallel with and somewhat above Poupart's ligament, on the right side, and raised up the peritoneum without entering the abdominal cavity. An aspirating needle was inserted, with negative result. The great tympanic distension of the bowels, and the inaccessibility and small size of the abscess caused so much delay that the patient's condition demanded a cessation of the operation before pus was obtained. A large drainage-tube was left in the bottom of the wound at its inner extremity, the rest of the incision closed by suture, and a dressing applied. For the next two days the patient was very near death, but he rallied, and on the twentieth day was able to be removed to the Massachusetts General Hospital. No further rectal examinations had been made because they were so extremely painful. About a week after entering the hospital, where he was under the care of Dr. C. B. Porter, he complained of a sense of obstruction when attempting to defecate, and a fluctuating tumor was felt in the rectum on the right side, which about one week later, on the thirtieth day of his illness, burst spontaneously, discharging about a pint of pus. From this time the patient made a rapid and complete recovery. He now

has a slight hernia at the place once occupied by the drainage-tube.

CASE III. Albert S., a nervous, undersized boy of thirteen, had eaten improper things and been chilled seven days before I first saw him. Pain had been the main symptom from the start. He had vomited once after medicine, but not again. The seventh day of his attack his bowels moved freely after a laxative. On the eighth day he was found in bed with red cheeks, a distended abdomen, great tenderness on the right side and none on the left. The greatest tenderness and pain were referred to the right lateral region of the abdomen half-way between the ribs and the ilium. Liquid food could be taken well. Nothing distinctive was felt per anum, nor at first externally. On the sixteenth day copious voluntary dejections occurred, and it was then possible to feel a resisting mass in the right iliac region, somewhat dull on percussion. The general condition was improving very rapidly, however, so that I felt justified in waiting. On the twenty-first day I inserted an aspirating needle at a point a little inside and above the anterior superior spine of the ilium. A very small amount of pus was obtained. The mother was now urged to have a surgeon see the child, but instead she called my successor. It did not seem best to him to operate. In two weeks the child was well, without any new symptoms.

CASE IV. This patient, aged twenty-nine, was in the early stage of general paralysis, but otherwise in good health, when this attack began. He had been constipated for a few days, when he suddenly felt an intense pain in the right side of the abdomen, shooting upwards into the chest, and also across into the left half of the abdomen. The right leg was drawn up. There was great tenderness in the right iliac fossa, with diminished resonance and a distinct sense of resistance. The axillary temperature on the fourth day reached 101.9° F., but then sank to normal. I was called on the third day, and on the next he was carried to the Massachusetts General Hospital in the ambulance, as he could not be properly nursed at home. The treatment consisted in rest, poultices, and deodorized tincture of opium. On the fifth day pain had greatly abated, but tenderness was still present. On the next day acute mania set in, but, nevertheless, two days later, when the patient was transferred to the McLean Asylum, having become calm again, there was no pain nor tenderness in the right iliac region, and complete recovery ensued. In this case the bowels moved freely on the first days of the attack. There were no gastric symptoms.

Of these four cases all were males, and three were under thirty years of age. In the first case we note long-continued constipation and the abundant ingestion of fig-seeds as possible causes of the attack, although it will be remembered that only twenty per cent. of all cases are women, and yet women are extremely subject to constipation. In the case operated upon the rectal examination should have been made earlier. In the case of the boy, who was first seen on the eighth day of the disease, I felt safer in temporizing because by that time the abscess might be supposed to have tolerably firm walls. In the last case the cardinal symptoms of appendicitis — pain, fever and a swelling — were all present, and yet the most violent manual struggles, in which it required three men to hold him, did not prevent the rapid absorption of the exudation.

Therapeutical Memorandum.

THE PHYSIOLOGICAL ACTION OF ARNICA MONTANA ON THE CIRCULATION.

BY H. A. HARE, M.D., (UNIV. OF PA.)
Demonstrator of Experiment at the Lectures and Instructor in Physical Diagnosis in the University of Pennsylvania.

ARNICA has been used for several hundred years chiefly as an external application for bruises, cuts, or like local injuries, and much less frequently, internally, as a stimulant in low fevers to the circulatory and even to the general nervous system. Used more largely by the older physicians than those of the present day, many of them asserted that it possessed value in intermittent fevers or in typhoid conditions, while even more favorable reports were made as to its effects in the treatment of peripheral palsies, as of the bladder and auditory nerve. It has also been used in the advanced stages of paralysis depending on centric lesions, after all tendency to inflammation has subsided.

Neligan found it useful in nervous headache.

Stroll claims that in the typhoid form of dysentery it should be regarded as a specific. Very few remedies, which have been so rarely used by the physician as has arnica, have found so great favor in the popular mind as has this substance. Nearly every household uses it whenever a sprain or bruise is produced, and it seems hard to believe that the results thus obtained exist only in the imagination of the patient, without any foundation, notwithstanding the fact that Garrod in a series of tests found that he obtained as good results with pure alcohol as with the tincture of arnica. Whatever may be the therapeutic conclusions drawn from empirical experience with the drug, it has certainly been found to be possessed of certain toxic properties, and for this reason it appeared to the writer worthy of a therapeutic study.

Viborg reports that it produces in the horse increased cardiac action, flow of urine, and warmth of the skin, followed by a full pulse, muscular tremors and depression. With large doses salivation was increased, and finally, insensibility to external irritants came on. Locally it acts, if concentrated, as a severe irritant.

When a dose of from five to ten drops of the official fluid extract of arnica root is injected into the jugular vein of a dog weighing from fifteen to twenty pounds, the pulse-rate and arterial pressure are for a moment depressed, but in the course of from thirty seconds to a minute return to their normal position. In about five minutes, however, the pulse-beats become one-third slower than they are normally, arterial pressure remaining unchanged, save that the pulse-waves usually produced by inhibitory stimulation give a greater range. If under these conditions the pneumogastric nerves be cut, the pulse instantly increases its rate considerably beyond the normal, though not to the point generally produced when the peripheral vagi are in a normal state. This difference was, however, more marked in some cases than in others. We may therefore conclude that the drug stimulates in small ordinary doses the vagal centre in the medulla, thereby producing a slow full pulse, and that it has an effect on the peripheral ends of the vagus for the reason that when these nerves are cut, the pulse-rate only increases somewhat. That this failure of the pulse to become very rapid after vagal section is not due to

cardiac depression, is proved by the strong pulse-waves and the increase in arterial pressure, rather than a fall.

When a much larger dose (five c.c.) is given to a dog of twenty pounds weight, the primary slowing does not take place, but in its stead the pulse becomes very rapid with a fall of arterial pressure which, however, soon recovers itself, the pulse still remaining rapid. Under these circumstances it was found that galvanizing the vagus nerves, even for as long as one minute and a half, failed to produce any cardiac slowing, proving palsy of peripheral vagi, and this was also proved by the fact that when the vagi were cut and their peripheral ends stimulated by small doses, large doses immediately produced a rapid rate, but no more than a momentary fall of arterial pressure, lasting perhaps twenty seconds and due simply to the sudden entrance of the drug into the heart *in massa*.

Arnica therefore slows the pulse in ordinary medicinal dose by stimulating the pneumogastrics both peripherally and centrally, increasing the fullness of each pulse-wave, and also slightly the arterial pressure. That the increased arterial pressure is chiefly due to increased work done by the heart is strongly indicated by the fact that in none of the experiments was arterial pressure influenced to any extent, by any dose, except when an enormous amount (5 c.c.) was injected rapidly into the jugular vein, when there was for the space of from ten to fifteen seconds a fall in pressure very evidently due to momentary heart-failure, as the pressure returned at once to normal as soon as the heart freed itself from the volume of the drug.

That the fluid extract used was pure I am confident since it was prepared by a reliable druggist especially for these experiments, and that no fallacy underlies the results of the experiments themselves seems proved by the fact that no less than seven tracings were taken from the carotid artery of as many different dogs, and in all cases the effects were the same.

Reports of Societies.

BOSTON SOCIETY FOR MEDICAL OBSERVATION.

G. F. STROSS, M.D., SECRETARY.

MEETING, November 7, 1887, DR. INGALLS in the chair.

DR. H. F. VICKERY read a paper on

APPENDICITIS, WITH REPORT OF CASES.¹

DR. WHITTIER said: Dr. Vickery's timely paper presents very clearly and concisely, the main features of the subject—appendicitis and its results, and suggests important topics for discussion. I think there is great danger of perpetrating a double error in all these cases. An error of delay in reaching a diagnosis or a guide for treatment, and an error in postponing surgical procedures when the diagnosis of appendicitis and its result has been made.

I am familiar with a number of cases of reported recovery from this formidable malady, treated on the expectant plan. But I am also painfully aware of the very large number of valuable lives lost because the diagnosis was unwarrantably delayed, or because surgi-

¹ See page 39 of this number of the Journal.

cal aid was not secured by the attending physician. If we assign the proper value to the very important additions to our knowledge of the subject of appendicitis and its results, recently made, and the largest and best contribution is that admirable monograph of Professor Fitz on "Inflammation of the Vermiform Appendix." I think we must concede that there is but little excuse for any practitioner who delays forming an opinion until it is too late for his patient to have the benefit of the most advanced methods of treatment.

I look upon this subject from a "medical" point of view, and if in such cases the opinion is formed, and it should be reached early in the progress of the disease, that one is dealing with appendicitis, a quick appeal should be made for surgical aid, and because there are, to-day, in this community, a very considerable number of surgeons, of the highest attainments in skill, and knowledge of all that pertains to this branch of their art, whose familiarity with all the minute details of safe abdominal section, and abdominal exploration is so great and whose frequent practice of the best methods have been followed by so good results; I hold that a physician who fails to avail himself of their skill, is inexcusable. My conclusion is, therefore, early diagnosis and early operation.

Dr. H. R. STEDMAN referred to a case of remarkable interest, reported by Dr. George W. Gay, at a recent meeting of the Society,² as showing how late it was possible for laparotomy to be successfully performed in similar cases. It concerned a young man who had an attack of localized peritonitis, in the neighborhood of the right iliac fossa. Two months from the beginning of the trouble, after several days of case, he had a return of the pain in great intensity and began to vomit. Four days later he had grown steadily worse, the pain and restlessness had increased and hiccough set in. In short all the symptoms tended toward destruction. Laparotomy was accordingly performed and the intestines which were adherent to the parietes over a space of from four to five inches were separated with the fingers from all morbid attachment. The patient made a good recovery in six weeks.

Dr. Stedman thought the prophylactic treatment of recurrent attacks exceedingly important. The fact that many of these patients were left with peritoneal adhesions often accounted for subsequent attacks of pain and actual return of the disorder. Consequently, movement tending to shake up the contents of the abdomen and put a strain upon these new attachments was an element of danger. From his personal experience as well as that of other victims of inflammatory attacks of this sort, in the neighborhood of the cecum, riding in jolting conveyances for any but comparatively short distances was sure to be followed by such symptoms. He believed this to be sufficiently common to make it always advisable to caution patients who have once had an attack of appendicitis to take no long rides or drives for at least a year afterwards, and then only in the easiest conveyances. Horseback exercise was especially fruitful, while on the other hand, quite active exercises or sports on foot in moderation, and riding in steam and horse-cars were, he thought, harmless. He had also known a return to be precipitated by protracted coughing.

Dr. SIEMAN inquired as to the possible influence

of heredity in this disease, and as to the mortality under the old expectant treatment.

Dr. VICKERY said he saw no reason to conclude that there was a possibility of hereditary influence. Statistics of mortality are wanting, but about thirty-three per cent. probably passed through all right. While the danger of fatal termination continues for at least two weeks under this, the expectant treatment, after the third day operative interference may be too late; by the third day is meant the third day from the attack of sudden pain, which denotes either the perforation of appendix or the lighting up of peritonitis. The inflammatory action has, of course, considerably antedated this.

Dr. BUNDY spoke of a case where currant-seeds were the offending bodies, and where the symptoms were decidedly those of typhoid, with relapse.

Dr. PAGE said that his experience had been that many cases get well by discharges through rectum.

Dr. F. B. HARRINGTON stated that the duty of the surgeon in a case of appendicitis in which both the rational and physical signs were present, is unquestionably to operate. By physical signs, I mean the evidence of a mass in the right iliac fossa or its immediate neighborhood.

Without such physical signs the diagnosis cannot be positive, although it may reach a considerable degree of certainty. When rational signs point to this condition, and the physical signs are absent, the surgeon is justified in delaying if the condition is not threatening. If the condition be very grave, and the patient going from bad to worse, with only an uncertain diagnosis of appendicitis, what should be done?

In a case recently referred to me by Dr. Whittier, in which it was impossible, owing to great distension, to make out any signs of appendicitis, and where he had advised that the only hope of recovery lay in operation, I found upon making an incision in the median line, and passing the hand to the right iliac fossa, that there existed a large abscess, the pus from which at once followed the removal of the hand. A counter-opening was made near the seat of the abscess, and the cavity thoroughly washed and drained.

The patient's pulse before the operation had been feeble, and varying from 140 upward. On coming out of ether she expressed herself as relieved, but she slowly sank, and died in six hours.

The operation, had it been performed a few days sooner, would probably have saved the patient's life.

In Dr. Vickery's case, the condition was very grave and threatening. The diagnosis was clear, but the only physical evidence was the small mass to be felt by the rectum. It seemed probable that this mass, not larger than an English walnut, was but a portion of a larger mass, which could not be felt by the abdomen, owing to the distension. An incision was made above Poupart's ligament, and the peritoneum followed down outside of the abdominal cavity, but no mass could be felt until the space between the external and internal iliacs was reached, when the same small mass could be felt through the incision, and with one finger in the rectum, could be grasped between the fingers. No pus was withdrawn by the aspirating needle. It did not seem best to open the abdominal cavity. Instead of following the track of the operation, the abscess developed, and at a later period opened into the rectum.

It seems to me that in these doubtful cases, where

² See Boston Medical and Surgical Journal, January 13, 1887.

the condition is extremely critical, it is best to make an exploratory operation.

Dr. J. S. GREENE accepted Dr. Whittier's remarks as applicable to cases where a diagnosis of perityphilitis is reasonably clear. He had lately had two cases of peritonitis suspected to be of typhilitic origin, in each of which the question of operation was duly considered and negatived.

One was a muscular, young Irish laborer, with rather high temperature, hurried breathing, diffused pain, and tympanitic distension, but without localized tenderness nor dullness. After five days, consulted with Dr. John Homans. Patient was removed by ambulance to Massachusetts General Hospital. He had peritoneal effusion and gradual absorption, and was discharged well after seven or eight weeks.

The other was an elderly, overworked man, with a history of one or more attacks of peritonitis several years previously. He was at home with abdominal pain on a Friday; attempted work on Saturday, jumping on and off his wagon, and this sealed his fate. Sunday he kept his bed, had diffused or not well-localized pain, moderate tympany, and slow pulse. No distinct dullness, but tenderness on palpation greatest at right iliac region. Consultation with Dr. Fifield on Tuesday, and operative interference negatived. Died Wednesday.

Autopsy by Dr. John Homans, 2d, showed general peritonitis and appendix sloughed and ruptured, fixed by old, firm adhesions to lateral wall of pelvis, below brim, and out of reach of any possible relief by operation, if such had been attempted.

Such cases, as to the question of operation, are in marked contrast with such a one, for example, as that of the boy, eleven years old, reported in Dr. Homans's series, where there was dullness on the right side, and where he (Dr. Greene) had appealed to Dr. Homans to operate within forty-eight hours after first seeing the case.

In reply to Dr. Webber's question whether lapse of time, exempt from recurrence after an attack of peritoneal inflammation, should weaken the inference or belief that the appendix had been the source of the trouble, Dr. Greene thought it should not.

In the fatal case just now mentioned, he had, in the absence of localized dullness, regarded the peritonitis several years earlier as a strong point in support of the presumptive diagnosis of appendicitis, afterwards confirmed by the autopsy.

Dr. M. H. RICHARDSON said that he was very much interested in this subject. He did not know to what conclusions the reader had come, not having been able to be present at the reading of the paper. He himself had come to the conclusion, after a somewhat limited experience, that an operation is demanded in many of these cases of inflammation in the region of the appendix. It seemed to him that in the majority of cases, the disease, if left to itself, is essentially extremely mild, or it runs a most violently fatal course. In the former class of cases, roughly speaking, the patient has little constitutional disturbance, and consults a physician only after the appearance of a tumor in the right iliac fossa. In the other class the inflammation takes a violent form from the outset, and a general peritonitis may occur in the first days of the disease. It is in these cases that operative interference is the most imperative, and the prognosis the most grave. The early distension of the intestines

makes a diagnosis from physical examination almost impossible, and the surgeon is obliged to do a laparotomy on the strength of his diagnosis formed from the history of the case.

In all cases where there is a tumor in the region of the appendix, there is no question as to the advisability of interference. In the more formidable class of cases there should also be no question, because, in the presence of a general peritonitis, there is nothing to be lost by an exploratory laparotomy, and everything to be gained.

The speaker had seen, during the past year, six cases of appendicitis. Five had recovered, and one had died. Two belonged to the class of formidable cases, two were of the mildest type, and two others were of moderate severity. In the last two cases there was a cake in the right iliac fossa, with very moderate constitutional disturbance. He saw them both in the second week of the disease. Both recovered perfectly without operation. The diagnosis was quite positive in both, being based upon the existence of pain, constitutional symptoms, and physical evidence in the region of the appendix. He should not now advise any operative interference in a similar case, but should have it watched with the greatest care, ready at any moment to meet a possible complication by surgical measures.

Two other cases presented a tumor in the right iliac fossa. In neither were there any constitutional signs of any moment. He evacuated the abscess-cavity in both by an incision parallel to Poupert's ligament—the incision for ligating the common iliac.

The other two cases were of the "écloupyant" variety. The first died the third or fourth day in a sudden collapse, before the question of operation had been presented to him. The other he saw with Dr. Elliott and Dr. Fitz. In this case, the disease, which seemed to be pursuing a steady and rapidly fatal course, was checked immediately by a laparotomy performed by Dr. Elliot. In this case, a brilliant success followed a most difficult operation. The diagnosis of appendicitis with general peritonitis was shown to be correct, and a large amount of fetid pus was evacuated, with almost immediate relief.

Dr. Richardson thought that it was in cases like the last, which he had taken the liberty to refer to, that all the judgment and courage of the surgeon must be brought to bear. He did not believe that the expectant treatment should ever be employed with such cases. It seemed to him true, however, that many such operations would prove unsuccessful. In cases like the fatal one alluded to, in which, at the autopsy, it was found that nothing could have been done beyond draining the peritoneal cavity for a septic peritonitis—an operation almost invariably unsuccessful in the hands of other surgeons, and wholly so in the experience of the speaker—in such cases we can, at least, give the patient a chance, and we do not leave him to die without an effort on our part to prevent such a catastrophe.

— We are assured, on the authority of an esteemed French contemporary, which publishes the item as a matter possibly worthy of imitation by enterprising French physicians, that a doctor in Australia puts the following notice in the papers: "*Je paierai la moitié des frais d'enterrement d'un bébé ou je ne ren-sais pas!*"

NEW YORK COUNTY MEDICAL ASSOCIATION.

STATED MEETING December 19, 1887.

DR. J. LEWIS SMITH read a paper on

PRESENT OPINIONS REGARDING THE PATHOLOGY AND TREATMENT OF DIPHTHERIA.

No disease in modern times, he said, had attracted more attention than diphtheria, since it was highly contagious and very fatal, was permanently established in many of the large cities in both hemispheres, and occurred every year epidemically in numerous rural localities. The result of the investigations in regard to the etiology of the disease had been to establish its microbic origin, but the microbe which was its specific principle was not clearly ascertained. Loewler, one of the most eminent authorities on the subject, had found that every diphtheritic patch contained many species of bacteria, which had been cultivated, but as they had not been isolated, the specific germ of the disease had not been determined. Another microbe, observed by Loewler, and described by Klebs in 1883, merited special attention. In some typical cases of diphtheria it was true, Loewler had not found it, but he suggested that it might possibly have died and been eliminated before the death of the patient. The bacilli was found in the exudate of thirteen cases, and cultures to the twenty-fifth generation inoculated in Guinea-pigs and birds produced a whitish exudation at the point of inoculation. The researches of Loewler and Cheyne lend support to the views expressed by Wood and Forman in their able report made to the United States Board of Health in 1882, who arrived at the conclusion that the two organisms, *micrococcus septicus* and *micrococcus diphtheritidis*, are specifically one, and that "diphtheria is a septic sore-throat, or is what was called a century ago, putrid sore-throat, with or without a secondary constitutional septicaemia."

That the bacillus was therefore the causative agent of diphtheria was rendered probable, and that systemic infection by the diphtheritic poison was not produced directly by the entrance of the microbe into the circulation, but by ptomaines which had sprung into existence through the agency of the microbe, was also the opinion of some of the highest authorities in bacteriology. It was seen that the investigations referred to lent support to the theory that diphtheria is primarily a local disease, and that in certain mild cases it never becomes constitutional, or is constitutional only in a very feeble degree. Nevertheless, those who believed that diphtheria was primarily constitutional based their opinion on facts which lent strong support to their theory, such as the incubation period of six or seven days in certain cases, the early occurrence of nephritis (even in twenty-four hours in malignant cases), and the existence of very severe and often fatal nephritis in certain cases where the disease of the mucous surface had been so trivial as to be scarcely appreciable. The mooted subject whether diphtheria is primarily local, or is primarily constitutional with local manifestations, or whether its nature in this respect varies in different instances, must, therefore, be considered as still undetermined.

As to the propagation of diphtheria, the statistics of Dr. C. W. Earle, of Chicago, showed that the disease was as severe and fatal in salubrious localities in the newly settled and mountainous states and territories of the Northwest, when it happened to be intro-

duced, as in the foul air of large cities, though dampness and decomposing animal and vegetable substances in rural localities as in cities, increased the prevalence of the disease. His statistics also showed that diphtheria may be communicated long distances by railways and probably by merchandise, and they demonstrated its extreme contagiousness from person to person. In the cities there was abundant and melancholy proof of the causative relation of foul air, whether arising from the sewers or from stagnant filth, to diphtheria, and Dr. Sternburg, in his recent valuable Lomb prize essay, had given the opinion (which seemed to be borne out by observations relating to the etiology of diphtheria), that the diphtheria germ, once deposited in damp and foul places, is probably propagated independently of the sick. Thus, in New York city prior to 1850, although foul sewers and insanitary conditions existed, there was no diphtheria; but in the decade following 1850 diphtheria was introduced, its germ made its way into the sewers, where in the filth underground it found a nidus for its propagation, and now whenever sewer-gas escaped into the domiciles of this city it was laden with the germs of this disease.

The amazing vitality and power of propagation of the diphtheritic germ were apparent when we reflected that it had permanently infected the filthy-flowing current of the sewers in every part of a great city, sewers which in their ramifications extended hundreds of miles. It was chiefly by the exposure of children to the sewer-gas, carrying with it the diphtheritic germ, which ascended from this widely-extending underground culture bed, and to walking cases of diphtheria, often so mild that there was little or no complaint of the throat or impairment of the general health, that the disease was so prevalent. In Dr. Smith's opinion the germ of diphtheria was of such a nature, and quickly became so established in a sewer city, that it could never be "stamped out," as cholera or yellow fever might be, by the active measures of health boards, or by legislative enactments, although these might doubtless do much in the way of protection.

He alluded incidentally to the possible communication of diphtheria to man from animals, and stated that recent investigations went to show that it might be thus communicated from poultry, and especially from pigeons, which birds, both wild and tame, were subject to the disease.

Having referred in detail to the differential diagnosis of diphtheria, and urged the desirability of enforcing the same precautionary measures in all doubtful cases as in unquestioned diphtheritic disease.

Dr. Smith spoke of the area of contagiousness in diphtheria, Dr. Lancy, he said, had cited cases to show that this area was small, being limited to a few feet. Dumez stated that, in a school in which the boys and girls in the same hall were separated by an open space of four yards width, diphtheria prevailed among the girls but did not affect the boys. Other instances were also mentioned showing that the area of contagiousness, like that of scarlet fever, was within narrow limits, and was, therefore, unlike that of pertussis and measles. The latter diseases, when they entered a domicile or asylum, usually affected all the unprotected children. Dr. A. V. Meigs, of Philadelphia, in his interesting paper published last year, on the propagation of the common infectious diseases of childhood, placed diphtheria with scarlet fever and ty-

phoid fever in one group. Diseases in this group, he said, seemed to be more subject to endemic or local influences than were measles and pertussis, not spreading over wide communities like the latter, and hence by strict quarantine and preventive measures their wide extension was more easily prevented. Those who had carefully studied the infectious diseases in children's institutions and elsewhere, would recognize the truthfulness of this distinction.

In speaking of the preventive treatment of diphtheria, Dr. Smith said that Dumas had recommended iodine as a prophylactic, giving to exposed children, in the course of twenty-four hours, a four-ounce mixture containing eight drops of tincture of iodide, and ten centigrammes (1.34 grains) of iodide of potassium. The most effective method of preventing diphtheria, however, was the isolation and disinfection of the apartments, in addition to preventing the inhalation of noxious gases wherever an outbreak of the disease had occurred.

Dr. H. B. Baker, of Lansing, Mich., had published statistics showing that in one hundred and two outbreaks of diphtheria the average number of cases where disinfection and isolation (either one or both), were neglected was sixteen, and the average number of deaths 3.23; while in one hundred and sixteen outbreaks in which isolation and disinfection were enforced the average number of cases per outbreak were 2.86, and of deaths .66. These precautionary measures, therefore, prevented thirteen cases and 2.57 deaths for each outbreak, or, in the total, 1,545 cases and 298 deaths in the year.

TREATMENT OF DIPHTHERIA.

The proper treatment of diphtheria was far from being determined; and a chief reason why there was such a difference of opinion in regard to the value of remedies, was because the disease varied greatly in severity in different localities, and at different times. In some epidemics a large majority recovered, whatever the treatment, (and even with injurious treatment), while in others a large proportion perished under the best possible remedial measures; so that statistics were misleading as to the value of therapeutic agents. In the year 1882, Dr. Lunn met with the following results from different remedies employed at the hospital of Oldenberg. In the fibrinous form of the disease the percentage of deaths under the various modes of treatment, was as follows:

By turpentine	8.30 per cent.
By resorcin	20.00 "
By bichloride of mercury	30.29 "
By ethioline	31.60 "
By tincture of chloride of iron	32.60 "
By bromine	46.70 "

In the septic form the deaths were as follows:

By tincture of chloride of iron	76.5 per cent.
By turpentine	81.0 "
By bromine	88.9 "
By resorcin	89.5 "
By bichloride of mercury	92.5 "
By ethioline	100.0 "

According to Lunn's observations, therefore, in the fibrinous form temperature was the most useful therapeutic agent; but in the phlegmonous and septic form, the chloride of iron was the most efficient. The cases of fibrinous diphtheria numbered 142, with 43 deaths; of the phlegmonous and septic form, 122 cases, with 103 deaths. In all the cases treated in the Oldenburg hospital, aggregating 296, 164 were fatal. After having spoken of the value of tincture

of chloride of iron, as observed by various writers, Dr. Smith took up the consideration of bichloride of mercury, which he said was at the present time regarded by many physicians as the most efficient agent at our command in the treatment of diphtheria. It was the most active and certain of the germicides employed in medicine, whether used locally or internally, and its use in diphtheria rested upon the fact that it quickly destroyed all micro-organisms. It was evident, however, that when this agent was employed as a spray in as strong a solution as was recommended by some, that it should be used with very great caution; and this was all the more necessary, of course, when the remedy was being given internally at the same time.

Dr. E. N. Oatman, of Nyack, New York, had reported that he lost but one patient out of twenty-three, when employing the following local treatment. Cotton is firmly wound around the end of a stick about the size of an ordinary lead-pencil; being drawn out as it is wound, and made to project beyond the end. This is dipped into a solution of bichloride of mercury two grains to the pint (1 to 3,840), and "passed into the throat until it touches the posterior wall of the pharynx. It is then instantly withdrawn and burnt." This treatment is repeated hourly, with a new swab each time, until the inflammation begins to subside, usually in forty-eight hours. Dr. Smith thought that the quantity of bichloride which could be safely given in twenty-four hours to children of various ages, was about as follows:

To a child of two years	one-sixth grain,
" " four "	one-fourth grain,
" " six "	one-third grain,
" " ten "	one-half grain.

Turpentine had been highly recommended recently by physicians of experience for its prompt action, when used locally as well as internally, in arresting the formation and extension of the pseudo-membrane, and as an antidote to the diphtheritic virus. Dr. Rewentauer had reported that an infant of two years, treated by other remedies, began on the fourth day to have symptoms indicating invasion of the larynx. Tracheotomy was resolved upon; but previous trial was made of pure turpentine in a teaspoonful dose. The result was that the croupiness ceased, the other symptoms improved, and the child recovered without tracheotomy. Delthil, by the alleged success of his fumigation treatment, appeared to have been the first to draw attention to the use of turpentine in this disease. His treatment was as follows: A mixture of 1 kilogramme (2 pounds) of coal tar, 8 tablespoonfuls of turpentine, 8 grammes (2 drachms) of resin of benzoin, and 100 grammes ($3\frac{1}{2}$ ounces) of cajuput oil; or a mixture of 200 grammes (7 ounces) of coal tar, 80 grammes (2 ounces, 6 drachms,) of turpentine; or turpentine alone, was constantly burnt in the sick room. The vapors arising from the burning mixture were tolerated by the patient and did not give rise to vomiting; while they appeared to aid in arresting the diphtheritic process. Schenker modified Delthil's treatment as follows: A mixture was prepared of 200 grammes (6 ounces) of coal tar, and 80 grammes (2 ounces, 6 drachms,) of turpentine; and of this, 50 grammes ($1\frac{1}{2}$ ounces) was vaporized at the bed-side four times a day, each use of the vapor occupying half-an-hour. His observations had led him to believe that the benefit from this treatment accrued chiefly from

the turpentine, and largely from its general effect upon the system. He therefore employed turpentine internally, in doses of 10 minims to one teaspoonful given from one to three times a day, in milk, sugar water, or gruel. At the same time he employed it as a spray. He also used alcoholic stimulation; and of 36 cases treated by the turpentine, 31 recovered. Röse, of Hamburg, treated 58 cases of diphtheria with turpentine, with the result of 35 per cent. recoveries. He gave it three times a day in teaspoonful doses, mixed with spirits of ether (ether 1 part, alcohol 3 parts), and also gave a teaspoonful of a 2 per cent. solution of salicylate of sodium every two hours. He used the turpentine cautiously in anæmic cases, and in those with feeble heart-action. Sigel stated that turpentine, in tablespoonful doses, reduced the temperature in 47 cases, in 14 of which the symptoms were so severe that the question of tracheotomy arose; but was postponed by the beneficial effect of the turpentine. Of the whole number of cases treated by him, with turpentine, 87, death occurred in 14.9 per cent.; while in those treated with bichloride of mercury, salicylic acid, potassium chlorate, etc., 32.5 per cent. died.

Sodium benzoate was another agent which had attracted considerable attention. Blondel had reported two hundred consecutive cases treated with it, without the loss of a single patient. He gave every hour one teaspoonful of a solution containing 15 grains of the benzoate to the ounce, together with one-sixth of a grain of sulphide of calcium in solution or granuli; and the throat was sprayed every half-hour with a 10 per cent. solution of the benzoate. At the same time the room was kept constantly filled with steam from a vessel containing carbolic acid, turpentine and oil of eucalyptus. Dr. I. N. Love recommended the sodium benzoate in 5, 10, or 15 grain doses, and, given in syrup, and cinnamon water, the solution was not unpleasant to take. Letzerich, Graham, Brown and Sanné, from experiments made on animals, considered this agent as a specific against the virus of diphtheria; while Dumas, who had not derived benefit from it in the actual treatment of the disease, proposed, as had been mentioned, that it should be utilized as a preventive.

Renou had had considerable success with the following method of treatment: To water constantly boiling, a teaspoonful of an alcoholic solution of carbolic acid, salicylic acid and benzoic acid is now and then added; so that in twenty-four hours 10 drachms (40 grammes) of carbolic acid, 2 drachms (8 grammes) of salicylic acid, and 4 drachms (16 grammes) of benzoic acid are employed. The quantity may be increased if the size of the room, the age of the patient, or the severity of the attack seem to require it. No local treatment apart from the inhalation, is resorted to; but constitutional treatment and sustaining measures are employed to the fullest extent. Barbier had used Renou's treatment for three years with much success. In 51 cases thus treated, 48 recovered. His method is to place in a petroleum stove an earthen pot full of boiling water, into which is put a tablespoonful of Renou's liquid every three hours for children between the ages of one and ten years.

Dr. Smith spoke in strong condemnation of the use of pilocarpine (which had been highly lauded by some authorities), on account of the disastrous results liable to be produced by it. He said he had seen it cause

symptoms resembling those in extreme œdema of the lungs.

In speaking of calomel, he quoted the favorable opinions regarding it expressed by Drs. George B. Fowler, William H. Daly, H. C. Wood, and others; but said that the experience of most physicians in New York who had tried it had been unsatisfactory.

Having referred briefly to treatment by quinine and by copoba and cubeba, he passed on to chlorate of potassium; and having presented the views of various authorities in regard to it, gave the following prescription, which, he said, had been long and favorably known in New York, and was probably more frequently written, with some variations in its proportions, than any other in diphtheria:

R.	Tinct. ferri chlor.	f 5 ℥-℥j.
	Potass. chlorat.	3 ℥.
	Acid. muriat. dilut.	gtt. x.
	Syr. simplicis	f 3 ℥.

Dose, one teaspoonful every one or two hours.

The tendency, however, had been in late years to diminish the amount of potassium chlorate, or even to omit it altogether, from its known irritating action on the kidneys, which are so prone to inflammation in this disease; and he thought it should probably be always omitted if any albumen appeared in the urine.

Dr. Smith mentioned, in passing, the use of bromine and permanganate of potassium, and the styptic treatment by the local application of Monsel's solution, and then spoke of papayotin in diphtheria. Rossbach had used this agent in a solution of the strength of one to twenty, frequently applied to the fauces. In very young children, a few minims might be placed on the tongue every five minutes. Dr. A. Jacobi stated that papayotin digests a thousand or two thousand parts (according to others, two hundred parts) of moistened fibrin, while not injurious to the mucous membrane. Dr. Jacobi had at one time lost confidence in its efficiency, but afterwards had reason to believe that the specimen employed was impure. More recently, he had found the drug to act well, and stated that diphtheritic membranes were dissolved in a few hours, in a few cases, after a day only. He employed a mixture of one part of papayotin, two parts of glycerine, and two parts of water.

Dr. Smith spoke favorably, also, of the solvent action of trypsin, which, like that of lime-water (by itself, of very feeble solvent power), was increased by being used in connection with an alkali. He suggested the following formula for a spray:

R.	Sodii benzoat.	5 ℥-℥j.
	Sodii bicarb.	5 ℥-℥j.
	Trypsin.	1 ℥.
	Ol. eucalypti	f 3 ℥.
	Liq. calcis	℥j.

Dr. C. A. LEALE said that after intubation of the larynx, as well as tracheotomy, one great cause of trouble complained of by operators was the difficulty of feeding the patient. To obviate this drawback, he had been in the habit of resorting to a very simple, and yet very efficient, method of introducing food, which, he thought, ought to be more generally known. This was by means of a Tiemann flexible-rubber, velvet-eyed catheter, No. 8, which could be readily passed through the nose, and then down into the stomach, even when the tube was in position. Then, with an ordinary syringe, liquid food of any variety could be injected through it at will. This device could be employed during unconsciousness, in

convulsions, etc., and, on account of its simplicity and easy application, it was desirable that it should be understood by all.

DR. FREDERIC S. DENNIS read a paper on

SELECTED CASES OF SARCOMA IN BONE, WITH PRESENTATION OF SPECIMENS AND MICROSCOPICAL SECTIONS.

This, he said, was more fatal than any other variety of malignant growth, and unless a radical operation were performed (which was successful in only a limited number of cases), death was absolutely certain to result from it. Rapidity of growth was also a marked characteristic. He had met with over fifty cases of sarcoma in bone altogether. Of these, the disease was situated in the lower extremities in fifteen, and it was to these fifteen cases that he desired to direct attention on this occasion; reserving a consideration of the cases in which it occurred in the upper extremities and other portions of the body until some future time. Having made some general remarks upon tumors and their classification, he stated that traumatism seemed to have a decided agency in the causation of sarcoma in bone. All sarcomata of long bones, he went on to say, might be divided, clinically and pathologically, into two groups—subperiosteal and central. The subperiosteal form of the disease attacked the extremities, and the central form the shaft of the bone; and the former was considerably more rapid in its growth than the latter. Egg-shell crepitation was characteristic of the central variety, but was not present in the subperiosteal. In speaking of the differential diagnosis of sarcoma from inflammatory neoplasms and carcinoma, he said that the former was a disease of early life, and was characterized by widespread metastases.

Dr. Dennis then proceeded to give the details of a number of his fifteen cases, calling attention to the special points of interest in each. The first case was one in which the sarcoma ensued upon fracture of the femur. The patient would not consent to an operation until the disease had reached an advanced stage, and when amputation was performed at the hip-joint he never rallied.

In the second case, in which the growth was also located in the femur, amputation at the hip-joint, performed within five months of the first appearance of the disease was followed by recovery. The prospect of final recovery, however, was still very doubtful, as three years was the shortest period at which such a patient could be pronounced free from the danger of relapse; and but a short time had as yet elapsed since the operation in this instance.

In the third case, in which sarcoma attacked the fibula as the result of an injury while skating on roller-skates, five years had now elapsed since the amputation, and it was certain that there would be no return of the disease.

In two other cases of sarcoma of the fibula (both subperiosteal), death resulted, and one of these, occurring in a female, was of exceptional interest, on account of the complete arrest of the disease during pregnancy, and its unusually rapid growth afterwards. After supra-condyloid amputation of the thigh, the disease recurred in the lower jaw, and three months after this had been removed it reappeared in the upper jaw. Still later, it made its appearance in the clavicle, and finally, in the lungs, when death resulted.

The early performance of a radical operation was the only safety in this disease, and Dr. Dennis said that he could not recall a single instance in which there had been a local recurrence of the growth.

Among the points to which he directed special attention in concluding his paper, were the following:

- (1) The importance of an early diagnosis.
- (2) The importance of complete removal of the disease by amputation of the part in which it is situated, and not by enucleation of the tumor.
- (3) The importance of carefully watching the subsequent history of the case.
- (4) The importance of recording all such cases coming under observation, together with the microscopical appearances of the growth.
- (5) The importance, in collecting statistics of this disease, of discarding all cases in which the microscopical appearances are not fully recorded.

Recent Literature.

The Curability of Insanity: A Series of Studies by PLINY EARLE, A.M., M.D. Philadelphia: J. B. Lippincott Co. 1887. pp. 232.

Thurnam's statistics of forty years ago of the curability of insanity have become classic. Nevertheless his investigations were practically without influence in reforming the methods of calculating and reporting recoveries, until in 1876, Earle took up the same line of inquiry. Thurnam was the first to tabulate *persons* and *cases* separately, and thus to clearly set forth the disparity between the number of admissions and recoveries and the number of individuals which they represented. He demonstrated conclusively the superiority of the method of computing the proportion of recoveries by the number admitted instead of by the number discharged. He also investigated with a thoroughness which his exceptional facilities alone made possible, the history as regarded permanency of recovery of two hundred and thirty-nine patients subsequent to their discharge from the York Retreat. The only other notable investigation in this line, is that of Mitchell in 1877. It was confined to tracing the mental condition of all patients in Scottish asylums during a certain period, twelve years after their discharge, as recovered. It is, by the way, somewhat remarkable that these three, prominent and reliable investigators of the curability of insanity, drawing their statistics from widely different sources, should reach practically the same estimate of the proportion of permanent recoveries. This is best expressed in Thurnam's celebrated formula, as quoted by Earle (p. 60): "In round numbers of ten persons attacked by insanity, five recover and five die sooner or later during the attack. Of the five who recover, not more than two remain well during the rest of their lives. The other three sustain subsequent attacks during which at least two of them die."

Comparing Thurnam's work with that of Earle we find that the latter emphasizes the same points, uses the same methods and reaches the same statistical results. Nevertheless, he has aroused such extended and effective interest as to bring about a decided reform in this class of statistical inquiry. Those acquainted with recent progress in matters of lunacy

will accept without question the author's statement in his preface, that the studies which the book comprises have greatly modified the aspect of insanity as a curable mental condition in the view of a large proportion of the persons most interested in the subject, have stimulated the search for other methods for the custody and care of a large part of the insane than that of collecting them in expensive and unwieldy institutions and have caused very important changes in the statistical methods of Massachusetts, in this country and in Great Britain, whereby the reader is informed of the number of *persons* as well as the number of *cases* that recover.

The secret of Earle's success is not far to seek for, although he takes the same direction as his predecessors, making their common position impregnable by his own accurate and varied tables of statistics; he goes farther, and not content with the mathematics of his subject, with the cold facts of figures, employs argument equally well fortified by examples from many sources, bristling with ridicule and driven home by constant repetition. It is his indefatigable zeal in exposing year after year in this fashion, in the reports his book comprises, false statistics of the curability of insanity wherever found, which has done the work. He condemns in vigorous style the spurious "recoveries from insanity" drawn from those cases of delirium tremens, of "alcoholic mania," who are simply drunkards suffering from the effects of debauch that have become sober. Under the head of "cooked statistics" he classes what might be called paper cures reported by political superintendents for the purpose of making cheap notoriety through the secular press. The delicate subject of the temperament of different reporters in influencing the number of recoveries, another element of error, he handles fearlessly but discreetly. Finally, the vast difference existing between the number of *persons* and *cases*, and its value in diminishing the number of recoveries — the burden of his whole argument — he presents most forcibly, giving for example detailed accounts of three women who contributed one hundred and two recoveries to the published statistics of insanity.

The outlook for the insane, as these investigations teach, is indeed a melancholy one. Nevertheless, with the heartiest appreciation of the solid worth of the author's work in establishing our knowledge of the curability of insanity on an accurate and scientific basis we can but admit that the tone of the book is needlessly discouraging. It is true that the writer's chief quest is the number of absolute cures or permanent recoveries, but the scope of his work does not, we think, preclude a fuller consideration of the value of recoveries from separate attacks than is accorded it. Even Thurnam, whose work he could claim with Earle, was "not a well-digested logically-constructed monograph," felt it necessary for the sake of accuracy to add that although the picture was an unfavorable one it was far from justifying the popular prejudice that insanity is practically an incurable disease, and that the view it presented was much modified by the long interval which frequently occurred between the attacks, during which interval of mental health (in many cases of two to twenty years), the individual had lived in all the enjoyments of social life. We miss, also, some allusion to a fact noted by Blandford among others, that statistics of this class refer to patients who have required asylum treatment,

and thus a number of cases of the most curable kind are omitted from the calculation. Another factor, though a small one, is the number of patients whose chances of recovery have been prevented by asylum treatment. Statistics on these points are, to be sure, well-nigh inaccessible, but the facts are unquestionable, and deserve to be mentioned and duly weighed, however little they may turn the scale, however unfortunate may be the deplorable tendency (which, by the way, the author believes to be still a growing one), of neglecting to send the bulk of the insane to asylums early in the disease, thereby increasing their chances of recovery.

These flaws, although legitimate subjects of criticism, are nevertheless negative faults and with certain defects of manner, such as much and wearisome repetition, make but a small blemish upon a contribution of great and lasting value.

The Surgeon's Pocket-Book. An Essay on the best Treatment of Wounded in War. By SURGEON-MAJOR J. A. PORTER. Revised and edited by C. H. Y. GODWIN. Third edition. 258 pp. 124 illustrations. P. Blakiston, Son & Co. 1887.

The above, as its title declares, is a hand-book for the military surgeon, rather than for a civil practitioner; but, notwithstanding this, it contains many facts which will be of interest to the latter, and, on occasions of emergency, of the greatest service to him.

The first edition (1875) was written by the author from data obtained by personal experience during the Crimean Campaign, the Indian Mutiny, and the Franco-Prussian War, to contest for the prize offered by the German Empress for the best essay on the practical treatment of wounded soldiers. It was this same contest that called forth the now world-renowned work of Esnarch. Although less successful, the "Surgeon's Pocket-Book" was of a character to receive a prize from such judges as Billroth, Von Langenbeck, and Sucin.

In addition to the above, the fact that it has reached a third edition is strong proof of its value and popularity. It represents an attempt to furnish a manual which shall give in the most concise and easily accessible form the knowledge required by a military surgeon, including all the advantages and improvements derived from modern experience and the latest campaigns of the English army. It is published in a very compact, neat volume of 258 well-filled pages, abundantly illustrated; the first twenty-four of which are devoted to the method of organization and equipment of a surgical corps, transportation of wounded, field hospitals, and the duties of a military surgeon, both in the field, with troops in action, or on hospital duty. The main portion of the book consists of a description of those injuries from projectiles or weapons used in modern warfare to which a soldier is exposed, classified according to the region of the body in which such wounds may occur. When necessary, the means of diagnosis are given, and the appropriate treatment. The details of amputations, excisions, and ligation of arteries are described in separate chapters. After discussing the complications liable to accompany such injuries; namely, erysipelas, hospital gangrene, phlebitis, pyæmia, osteomyelitis, etc., the remainder of the essay is devoted to a description of the sanitary condition and medical management of troops, both in camp and on the march; instruction about location of

tents, barracks, and latrines, ventilation, water, methods of testing its purity and filtration, etc. In four appendices is given a formulary for antiseptic solutions, unguents, etc., lists of materials for surgical dressings and necessary drugs, with directions for the most convenient way of packing for transportation and for their use. Finally, a list of supplies copied from that used on the Nile expedition during the late Egyptian campaign, giving the equipment of twelve men for one hundred days. The book is well written, and contains much information on subjects usually omitted in such hand-books, and, although treatment and methods of operation (though good) may not be in all respects what is now considered the most approved, still the remainder of the essay is alone enough to make it a work of interest and value to every one liable to be called to fulfil the duties of a military medical officer, or of an analogous position.

Health Lessons. A Primary Book. By JEROME WALKER, M.D. pp. 194. New York: D. Appleton & Co. 1887.

Among the numerous publications relating to elementary hygiene, which have recently appeared, this is one of the best. The author says in his preface: "In this little book the aim has been to teach health-subjects to young children in a truthful and interesting way, and by somewhat different methods than those usually employed." Dr. Walker has succeeded in presenting the subject of hygiene in a manner both intelligible and entertaining. Technicalities are almost entirely excluded, so that the youngest children may readily comprehend the subjects presented.

The illustrations form a very attractive feature of the book: they are all new and original, and show a marked improvement over the hackneyed wood-cuts of older books of the same sort. Comparative anatomy is occasionally called in to aid the young learner.

As an example, an illustration upon page 129, intended to teach the uses of the bones, shows in one picture a man, a horse, a turtle, a tree in foliage, and a house. In another picture on the same page are presented the skeletons of a man, a horse, a turtle, a tree in winter with bare branches, and the frame-work of a house.

With reference to the alcohol question, the author says, "While there is special teaching as to the effects of alcoholic stimulants and of narcotics upon the human system, they are presented in such a way, in connection with other subjects, as is believed will appeal most forcibly to the imagination and the reasoning powers of children, and leave the strongest impressions upon the mind as to the evils attending the use of these things."

The experiment has been tried in the Lahor district, India, during last year, of vaccinating from a young buffalo instead of from a calf, and the results were in every way satisfactory. What led to the experiment being made was the prejudice of the Hindus against being vaccinated from the young of the sacred cow, while, on the other hand, the standing objection of the people to allowing the lymph to be taken from the arms of their children rendered it almost impossible to obtain an adequate supply of lymph.

THE BOSTON Medical and Surgical Journal.

THURSDAY, JANUARY 12, 1888.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States and Canada; \$6.00 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 94 Boylston Street.

All letters containing business communications, or referring to the publication, subscription or advertising department of this journal, should be addressed to the "Manager of the Business Department," Medical and Surgical Journal, 94 Boylston Street.

Remittances should be made by money-order, draft, or registered letter, payable to

CUPPLES AND HURD,
94 BOYLSTON STREET, BOSTON, MASS.

REPORT OF THE SURGEON-GENERAL.

THE report of the Surgeon-General of the United States Army for the year ending June 30, 1887, is an exceedingly interesting document, and in no part more interesting than in the pages devoted to the hygiene of the army. An important part of the duty of a medical officer is the supervision, under the direction of his immediate commander, of the hygiene of the post to which he is attached, and the recommendation of such measures as he may deem necessary to prevent or diminish disease among the troops. Army regulations now provide that he shall examine, at least once a month, the sanitary condition of all buildings belonging to the post, the rations, the water supply, the drainage, the clothing and the habits of the men, and shall report thereon to the commanding officer with such recommendations as he may deem proper. A copy of each report, with the action of the commanding officer thereon, is forwarded to the surgeon-general.

In regard to these reports the surgeon-general says: "By far the greater portion of the sanitary measures recommended were carefully considered, practical, and capable of being easily carried into effect with the means at command, and it is gratifying to note, the medical officers as a rule received the cordial support and co-operation of their immediate commanders in their efforts to increase the health and comfort of the commands to which they were attached." The want of such co-operation between commanding officers and their medical subordinates was at times a source of ill health among the troops during the war, and that these efforts have been attended with a large measure of success is evidenced by the diminished rates of sickness and mortality in the army for the year 1886, as compared with previous years.

The care with which some of these recommendations were made is shown by the copious extracts given. The fullest reports given are on the subject of the clothing furnished the troops serving in the southern portions of the country. Medical Director

E. P. Vollum, in endorsing the recommendation of Assistant Surgeon Carter, post surgeon at Fort Ringgold, Texas, states that the United States stands alone in the measure of forcing its troops to wear the same uniform during all seasons and in all latitudes; and in the twenty-four degrees embraced within the boundaries of our country there are some places as hot as any occupied by white troops anywhere in the world. In this hardness in adapting the clothing of our troops to the climate, we stand about where the English did in the first days of their occupancy of India.

Where troops along the southern border are allowed to dress somewhat according to the suggestions of their instinct, and the necessities of the climate as found out by experience, which is sometimes done on scouting trips, they throw off their woollen uniforms, and use any light garment they can find. Officers who were on the campaign in Arizona and Sonora, that was made against Geronimo's band, report that the infantry marched most of the way in drawers and undershirts, and that after the men once experienced the luxury of wearing these light garments they never put on the blue woollen trousers again till their return home.

The medical public will agree most heartily with the Surgeon-General in his statement in regard to the index-catalogue: "The usefulness of this work to the medical writers and teachers, not only of the United States but of other countries, can hardly be over-estimated, and it is very desirable that it should be completed as rapidly as possible." The first part of Volume IX is already in press.

A portion of the new museum and library building is already occupied, so that the most important part of the pension records, and of the library, have been made secure from fire. The museum has been enriched by the plaster casts and bony preparations of the late Prof. F. H. Hamilton, of New York. It is to be hoped that the recommendation made in the last report, and renewed this year, that authority be given for the publication of an illustrated catalogue of the museum will be granted.

The number of medical officers permanently disabled is becoming a matter of serious embarrassment to the department, and an increase of twenty assistant surgeons is recommended.

A MILITIA AMBULANCE CORPS FOR NEW YORK.

A RECENT general order, issued from the office of the Adjutant-General of the New York National Guard, provides for the establishment of an ambulance corps modelled upon the corps recently established in the regular army. For a regiment or battalion the corps will consist of the hospital steward, and three enlisted men from each company of seventy-five men, and two enlisted men from each company of less than that number, and two corporals may be included in the detail. The men are to be detailed on

the recommendation of the senior medical officer, and shall be relieved from such duty on the application of the medical officer having charge of the corps to which they are attached. The men are not relieved from regular duties except when on duty with the corps in active service. The corps is to be under the immediate orders, control and instruction of the senior medical officer of the command to which it belongs.

An annual course of instruction to be given by the medical officers includes rudimentary instruction in the diagnosis and treatment of the common accidents and diseases to which the militia are exposed, stretcher drill, and matters pertaining to the transportation of the wounded, personal and camp hygiene. At the close of the course of instruction the men are to be examined by a board appointed by the commander of the brigade with the approval of the surgeon-general. After passing the examination enlisted men will be permitted to wear at all times a badge distinctive of the ambulance corps of the state. When actually on duty men of the corps will wear an arm badge (brassard) of white cloth with the red cross.

The New York organization differs from that of Massachusetts in attaching the corps to the regiment rather than to the brigade, and in detailing men previously enlisted, rather than enlisting men specially for the corps.

Each method recognizes the necessity of a special training for the duties of stretcher bearers, and each ought to give good results. With the system established in the regular army and in the militia of two States, other States ought soon to follow the example.

The JOURNAL watches with pride the establishment of these various ambulance corps, which has followed its suggestion of September 25, 1884.

CIRCULAR INSANITY.

THERE is a kind of mental alienation which, although its existence has impressed itself on medical literature from ancient times, has only within the last thirty-four years obtained, as it were, the right of domain in the nosology of diseases of the mind. This form of insanity goes by the name of *folie à double forme*, "circular insanity" or "alternating insanity."

In January, 1851, a memoir was read before the Academy of Medicine, Paris, by M. Baillarger, with the following title: "Note Concerning a Kind of Madness whose Paroxysms are characterized by Two Regular Periods, the one of Depression, the other of Excitation." Baillarger's paper contained reports of seventeen cases, a part of which had come under his own observation, and a part were borrowed, on which were founded the conclusions which led him to add another group to the established groups of mental affections. To this new kind of insanity he gave the name of "*folie à double forme*." He explained the word *paroxysm*, as used in his definition, as meaning

"the reunion of two periods of excitation and depression, following each other without intermission." Any alleged intermittence between the two phases of the disease he affirmed to be, not a return to complete sanity, but only a minor degree or "shade" of one or the other of the phases. He pointed out the types which this malady may assume in its course, and indicated certain predominant symptoms which may characterize the period of excitation, such as nymphomania, satyriasis, and dipsomania. He, moreover, dwelt on the essential incurability of the disease.

A few days after the reading of M. Baillarger's communication, M. J. Falret, Sr., published the first part of his "Clinical Lessons on Mental Disease"—a work embodying a part of a course of lectures delivered by him at the Salpêtrière. In this brochure, we find essentially the same form of mental alienation described under the name of *folie circulaire* (circular insanity), and proof that these two alienists, Baillarger and Falret, had been simultaneously exagitating and elaborating the same train of ideas as deductions from independent observations. Any question as to the right of priority seems frivolous under the circumstances. The main difference between Baillarger's conception and that of Falret, is that the latter insists upon the existence of a lucid interval of greater or less length between the maniacal stage and the melancholic stage. Just a fortnight after Baillarger's communication, Falret read a paper before the Académie with the title: "Memoir on Circular Insanity, a form of mental disease characterized by the successive and regular reproduction of the maniacal state, the melancholic state, and a more or less prolonged lucid interval." In this memoir, Falret endeavored to show that the passage of mania into melancholia, and *vice versa*, had been observed from the earliest times as an accidental occurrence, but that it had not been sufficiently noticed, or, at least, it had not been expressly stated, that there exists a certain category of lunatics in whom this succession of mania and melancholia manifests itself in a continuous and quite regular manner. This fact, he says, had seemed to him sufficiently important to serve as the basis of a particular form of mental disease, which he called *circular insanity*, "because the existence of this kind of madmen revolves in one and the same circle of morbid states, which reproduce themselves without cessation, as if fatally, and are separated by a very brief interval of reason." The "melancholia" which he describes is "an extreme physical and moral depression, amounting sometimes to complete suspension of the intellectual and affective faculties." The period of expression is much longer than the period of maniacal exaltation. Moreover, "this is one of the most grave forms of mental alienation, which hardly admits of any lasting amelioration." Falret, lastly, shows the importance of heredity in the production of this species of insanity, and insists upon its greater frequency in women than in men.

As for the lucid period which Falret intercalates

between the melancholic and maniacal stages, there is no doubt, as Ritti observes,¹ that a certain proportion of cases bear out this view of the evolution of this form of insanity. At the same time, in the great majority of cases, the lucid interval, if it exists at all, is so short as to be inconspicuous. More commonly, the two characteristic phases of the malady imperceptibly shade into each other, the patient passing from a state of extreme melancholy into less and less pronounced states of depression, and so on, going through a regular pathological cycle into maniacal excitement, and back again into melancholic depression or stupor.

The treatises of Baillarger and Falret seem definitely to have established the fact that mania and melancholia may, in certain cases, be so welded together as "to constitute a morbid unity composed of two periods, as the attack of intermittent fever is a morbid unity formed of three stages."² Only the unity which was the creation of Baillarger embraced somewhat more than was included in the partial conception of Falret, who really saw only one variety of the morbid species which the former has so well defined. Baillarger's *folie à double forme* comprehends all kinds of chronic mental alienation which are characterized by alternating periods of mania and melancholia, whether these follow each other in quick succession by an apparently abrupt transit, whether they dovetail into each other, or whether they are separated by a lucid interval of greater or less length.

Since the publication of the treatises to which reference has been made above, quite a voluminous literature has accumulated on the subject, and the terms "circular insanity," "*folie à double forme*," with the complexus of phenomena which they connote, have now a generally recognized place in the nosology of mental diseases. In the able and exhaustive work of Ritti, about all that is known respecting this interesting department of mental diseases is well summed up and coördinated.

THE NEW YORK QUARANTINE STATION.

THE first of the year Mayor Hewitt made public the report of a committee of the Academy of Medicine, consisting of Drs. C. R. Agnew, E. G. Janeway, A. Jacobi, Stephen Smith, T. Mitchell Prudden, H. M. Biggs, and Richard H. Derby, whom he had requested to make an examination of the Quarantine establishment, and point out its defects and requirements, to estimate the sum necessary to be appropriated by the State in order to secure the improvements demanded, and to suggest whether the city should provide any further temporary hospitals in case of an outbreak of cholera. By this committee the manifest deficiencies of the New York Quarantine have again been pointed out, and they call upon the Legislature to take prompt

¹ *Traité Clinique de la Folie à double forme*, Paris, 1885.

² Ritti. *Loc. cit.*

and active measures to remedy the existing evils. The plans to accomplish the desired results should, in their opinion, be speedily prepared by the State officers. "If there be neglect in this matter," they say, "and cholera, which has threatened to invade the port for more than three years, and has recently been brought to Quarantine, should appear in the spring, and, favored by warm weather, pass an imperfect quarantine, and reach New York City or Brooklyn, or possibly extend beyond to near or remote places, public opinion would seek out the blameworthy and visit them with a condemnation which no seclusion would be deep enough to smother or mitigate."

In transmitting this report to Governor Hill, the Mayor remarks in an accompanying letter that it discloses a condition of affairs which calls for the immediate action of the Legislature, and that the danger of delay is too imminent to admit of any postponement whatever. He then goes on to say that if, in the wisdom of the Legislature, a commission shall be formed to rebuild the Quarantine establishment, so as to bring it up to the highest ideal standard of modern scientific knowledge, he can pledge the coöperation of the city authorities and of the medical profession, who have shown themselves to be fully alive to the great dangers of the situation.

On the first business day of the session of the State Legislature, a bill was introduced into the Senate, it is stated, at the instigation of the Quarantine Commissioner, Thomas C. Platt, which makes the salary of the Health Officer, \$10,000 a year, reduces the Quarantine fees, and provides for their disbursement in the payment of salaries and other necessary expenses.

MEDICAL NOTES.

—The *Army and Navy Journal* quotes an electrician as proposing the use of nitrate (sic) of amyl as a filling for shells, instead of gun-powder. "A few gallons of this nitrate dashed upon the deck of a warship would soon render her crew helpless." It is not necessary for the shell to penetrate the ship's walls, for if the shell was dropped on deck the ventilating apparatus employed on most iron-clads would suck the vapor down into the hold and aid in the overwhelming of the crew. Meantime, the attacking force tows the useless ship away, and at leisure lifts out the dead or senseless men.

—An interesting incident is given in the *Lancet*, regarding the late Sir William Smart, of the British Naval Medical Service. In the course of duty he had never been under fire, although from indulging his curiosity as a spectator of the siege operations at Sebastopol he had run some risk. But it so happened that in China he was on one occasion accidentally wounded by a pistol bullet. It entered above the wrist, ran up the arm, and lodged between the radius and ulna just below the elbow. He said he could sometimes feel this ball get in between the bones when bending the joint, and cause sudden stoppage of the

movement of flexion. With characteristic resolution, Sir William kept this a secret throughout his life, even from his family, because he feared that if known it might injure his prospects of employment as a hospital surgeon. Shortly before his death he expressed a wish that some mention should be made of his wound, the scar of which was visible, in order to show that though a man may have a bullet encysted in his right forearm, he may still be a good operator.

—Dr. H. Chataing made a medico-legal study of poisoning by chloride of potassium for his inaugural thesis based on eleven collected cases, according to the report of this thesis in the *London Medical Record*. Cases of poisoning by chloride of potassium are rare in France, where the drug is little given as a medicine, but is more frequent in Germany, and still more so in the United States. They are due either to mistakes in dispensing, ignorance, or — though not often — to attempted murder or suicide. The symptoms are the slate-coloration of the skin, which is either uniform or in patches, and is sometimes accompanied by jaundice. The urine becomes scanty, dark-colored, and contains albumen. In subacute cases the drug acts as an irritant poison, giving rise to diarrhoea, vomiting, and gastric ecchymoses. In acute cases there are cardiac symptoms, and alteration of shape of the blood-corpuscles. The best treatment is milk as a diuretic, pilocarpine as a diaphoretic, and stimulants prevent a collapse. The maximum dose permissible is from six to eight grammes in the twenty-four hours.

NEW ENGLAND.

—George D. Hersey, M.D., of Providence, has been appointed visiting surgeon to the Rhode Island Hospital, to fill the vacancy caused by the death of Dr. Edward T. Caswell.

NEW YORK.

—The President of the Board of Health, Mr. Bayles, having recently made a report on the sanitary condition of the City Hall, which declares that this is so bad that immediate steps should be taken to prevent risk to the lives and health of the occupants of the building, all the offices have been temporarily vacated, and the Common Council have ordered the Commissioner of Public Works to make, without delay, such changes and improvements in the drainage, plumbing and ventilation as will put the building in proper sanitary condition.

—Up to Saturday, January 7th, the Hospital Saturday and Sunday fund amounted to about \$20,000.

—At the meeting of the Academy of Medicine, held January 5th, memorial papers were read by Dr. J. L. Corning on Dr. T. R. Varick, by Dr. J. C. Peters on Dr. Middleton Goldsmith, by Dr. S. D. Hubbard on Dr. Jared Linsly, and by Dr. Francis Delafield on Dr. Alonzo Clark.

—Dr. Newton M. Shaffer has commenced, under the auspices of the trustees of the institution, a course of free lectures on Orthopaedic Surgery, at the New York Orthopaedic Dispensary and Hospital at 126 East 59th Street.

Miscellany.

OBITUARY.—DR. WESLEY M. CARPENTER.

THE profession in New York and elsewhere has been greatly shocked by the sudden death of Dr. Wesley M. Carpenter, who was found dead in his bed on the morning of Jan. 7th. For some weeks he had complained of rheumatic troubles, but had been about as usual, and the cause of death was Bright's disease. He was about fifty-five years of age, and was born in Erieville, N. Y. He was graduated from the College of Physicians and Surgeons of New York, and for a number of years practised in the vicinity of his native place. Almost twenty years ago he removed to New York City, where he engaged in practice for about five years, when he retired in order to devote himself to medical literary and scientific work. For many years he has been the most active worker, with the exception of Dr. Shrady, the editor-in-chief, on the staff of the *Medical Record*, and the energetic and efficient secretary of the Medical Society of the County of New York. At the time of his death he was also Corresponding Secretary of the New York Academy of Medicine, Clinical Professor of Medicine at the University of the City of New York, one of the curators of Bellevue Hospital, and editor of *The Epitome*, a monthly retrospect of American practical medicine and surgery. He compiled an "Index of Surgery," and other works, and was one of the collaborators on "The American Encyclopedia of Surgery." His many genial qualities made him a general favorite in the profession, and he will be greatly missed at all the meetings of the medical societies, at which, in connection with his work on the *Record*, he was so constant an attendant.

of mental disturbance due to chronic nephritis. I was told by one of the physicians who attended him that the man was full of delusions. He thought that his wife and others were persecuting him.

"I saw another interesting case a year ago last Christmas. This occurred in the practice of Dr. Mullin, of Hamilton, Canada. Here a medico-legal question arose. It was, whether or not the man was in a condition to make a will. There was no doubt as to the existence of chronic Bright's disease. The mental condition was peculiar. He believed that his wife and others had designs upon his life, and it was with difficulty that he could be persuaded to take food. He thought that people were persecuting him. Although he gave a very intelligent account of himself, it was not considered advisable that he should make his will at that time. He was placed upon a somewhat more active treatment than he had previously received. This man subsequently did well, his mind had cleared, and he recovered sufficiently to get about and to make his will."

COMPARATIVE MORTALITY IN ENGLAND AND IN AMERICA.

THE imperfect system of registration of vital statistics in America prevents the possibility of a useful comparison between the rates of mortality in England and in America. The rapid growth of life assurance in the United States has accumulated, however, a mass of statistics of mortality of still greater value for estimating the duration of life in that country than the results of any system of civil registration of births and deaths yet existing. During the thirteen years 1859-72, the number of life policies existing in the United States increased from 50,000 to 800,000. After 1872 the number of policies remained comparatively stationary for some years, but more recently the number has probably again increased rapidly. Fortunately for the present purpose—a comparison of the value of life in England and in America—a valuable series of experience tables, based on the life and mortality statistics of thirty American life assurance offices, was published a few years ago. The basis of experience upon which these American tables are constructed is sufficiently large to give the results a very definite value. The tables dealt with more than half a million of policies existing at the end of 1874, as well as nearly 50,000 previously lapsed by death, and nearly an equal number that had lapsed by surrender or discontinuance of premium—in all, with more than 600,000 policies, covering considerably more than 4,000,000 of years of life under observation. Among the more interesting results shown by these tables, it may be noted that the expectation of life of insured males in America at twenty years of age is 42.1 years, and exceeds by one year the expectation of males in England by the English experience tables; this excess in the male expectation of life in America is maintained through life, although it steadily decreases, until the advanced age of eighty-four, when the difference in favor of American life disappears. With regard to female life, the expectation of life at the age of twenty is precisely the same (40.8), both by the American and English experience tables; but afterwards, and until the age of forty-seven, the American expectation somewhat exceeds the expecta-

MENTAL AFFECTIONS ASSOCIATED WITH CHRONIC BRIGHT'S DISEASE.

At a recent meeting of the Philadelphia Neurological Society, Dr. William Osler made the following remarks on the above topic, as reported in the *Polyclinic*:

"I would like to make some reference to the occurrence of certain mental affections which come on in connection with chronic Bright's disease. It is well-known that certain mental phenomena occur in connection with chronic renal diseases besides simple uræmic coma. I have reported one case of violent mania in a man aged forty-two years, the subject of Bright's disease. When brought to the hospital he had been maniacal for three or four days. He subsequently became comatose and died. A very interesting case was recently under my care in the University Hospital. A man was brought to the hospital Thursday evening. I saw him on Saturday. He was then quiet, in a semi-dozing condition, but could be aroused, and gave a very interesting account of himself. The whole clinical picture was that of chronic interstitial nephritis. I thought it not improbable that the man might pass into a condition of coma. There was nothing to attract special attention to his mental condition, and I did not regard his condition as critical. That night he got out of bed, in the absence of the attendant, wandered about the ward, and finally jumped out of the window. It was subsequently learned that, before admission to the hospital, he had been violent, requiring two or three men to hold him. We were not told this when he was brought to the hospital. I have no doubt that this was an instance

tion according to the English tables, while after the age of forty-seven the difference is in favor of English life, increasing to a year at eighty years of age. One other marked feature disclosed by a comparison of these American and English experience tables is that in America expectation of life among insured females is lower than among insured males after the age of fifty-three years, while it is identical with that of males. It is well known that by all the principal English tables expectation of life among females exceeds that among males after the age of thirty-five years, and shows an increasing excess to the end of life. These differences between the expectation of life in America and in England relate, it should be remembered, solely to insured lives, mainly belonging to the middle and upper classes. If similar statistics were available for the general population, very much wider differences between the mean duration of life in America and in England would probably be shown. — *The Lancet*.

BROUARDEL ON HERMAPHRODISM.

PROFESSOR Brouardel very carefully epitomized the characteristics of this curious condition in a clinical lecture which he recently delivered, and which is reported in the *London Medical Record*, December, 1887. He pointed out that hermaphroditism can only be complete so far as the internal organs are concerned. An individual may have one ovary and one testicle, but not a scrotum and a vulva, for it is evidently impossible to have a joining and a separation simultaneously. Pseudo-hermaphroditism generally consists of an arrest of development for the male sex (hypospadias) and an excess of development for the female sex (hypertrophy of clitoris and possible obliteration of vulvar orifice). If any difficulty be experienced in distinguishing the sex, the expert should examine the general bearing of the individual — the voice, gestures, face (beard?), the shape of the neck and members, which, as a rule, are less muscular in the female than in the male, the arrangement of the pubic hair, circular in the female, triangular with the apex pointing to the umbilicus in the male. The essential, of course, is the detection of the testicles and the ovaries, but this, of course, is often difficult or impossible on account of their non-migration. They may simulate a painful gland, and may even give rise to the diagnosis of a vaginal hernia. The absence of uterus does not signify much. With hypospadias males who disguise their sex because they prefer to utilize their cavity as a vagina, the male sex may be affirmed if the observer can trace (1) a characteristic depression, resembling a cutaneous-mucous raphe, at the base of the rudimentary penis, pulling it down; (2) the absence of a hymen caruncle, myrtiliformes; and (3) the absence of the labia minora. Hypospadias may have fortuitous discharges of a sanguinolent nature which may easily be mistaken for the menses.

A CASE OF HYDATIDS IN BONE.

MR. LEACOCK describes in the *Australian Medical Gazette* for November, 1887, a case of this rare disease of bone. It occurred in a male, aged forty (at the

time the diagnosis was made). At twelve he was injured in the left knee by a cricket ball and had trouble from it off and on. Eight years later he was kicked by a horse on the same knee; from this injury he never quite recovered, the joint being always weak and sometimes a little swollen and painful. Thirteen years later these symptoms (after much walking), became so aggravated as to keep him in bed much of the time for six months. Since then — that is for the last seven years — there has been inability to completely straighten the limb, frequent pain, and permanent though slight enlargement of the joint. The patient came under Mr. Leacock's care about four months ago, through having struck the knee violently against a post. For a fortnight he kept his bed, with all the usual local symptoms of acute synovitis, but little or no constitutional disturbance or rise of temperature. At the end of that time, the pain having greatly subsided, he left his bed on crutches, but could not put his foot to the ground, and the pain gradually returning, after two or three weeks he was compelled to take to bed again. All the usual means for obtaining absolute rest to the joint were adopted. Extension, instead of relieving, seemed only to increase the pain. There was no symptoms, either local or general, of suppuration. There was only a slight increase of swelling about the knee; very little effusion in the joint, the permanent seat of pain being referred more particularly to a spot on the inner condyle of the femur. In addition, there were the usual electric shock pains and startings, aggravated at night.

Finding, after about a month's treatment, that absolutely no improvement took place; that the patient's health was beginning to break down from constant pain, and that he himself was anxious for relief at any risk, operation was proposed and accepted. On opening the joint, a small amount of flocculent lymph was found with slight erosion of the articular cartilages, and on digital examination a perforation admitting the tip of the finger, between the condyles of the femur, apparently communicating with a cavity in the end of that bone. There was chronic thickening of the ligaments and fibrous tissue of the joint, but no pus; no hydatid cysts were seen in the joint, and of course none were expected. On applying the saw to the condyles of the femur, the instrument did not meet with the usual resistance; the bone in fact, was a mere shell, in some parts scarcely thicker than paper. Such being the state of affairs amputation was the only resource, which was done at once in the lower third of the thigh.

On examining the removed limb, the lower end of the femur was found hollowed out into one large cavity, stuffed full of hydatid cysts, from the size of a small pea to nearly an inch in diameter. The cancellous structure in the head of the tibia was undergoing fatty degeneration, and in the popliteal space was an ounce or more of broken-down soft tissue, evidently a commencing abscess, though not yet converted into pus.

The stump healed almost entirely by first intention.

Apart from the rareness of hydatids in bone, the interest of the case mainly consists in the inquiry as to how long they had been there, and whether injuries to the knee affected their activity in any way, so as to lead to an increase of production, and consequent inflammatory action.

AN EPIDEMIC OF PNEUMONIA AMONG CHILDREN.

DR. F. TROSSAT describes in *Lyon Medical*, December 18, 1887, an epidemic of pneumonia occurring in Chalon-sur-Saône, which well illustrates the infectious nature of the disease. There had been considerable pneumonia in the department during the months of February, March and April, but the cases were so scattered that no contagious influence could be determined. The first case in this village (St. Léonard la Salle), was a child of five and one-half years, taken sick February 28th. March 7th, children in four different families were taken sick with the same disease. March 9th, three more cases occurred, and on the 11th, one more. All these nine children, aged from two to six years, went every morning to a sort of day-nursery (*asile maternel*), where they stayed till 9 a.m. For more than a month there had been no case of pneumonia in the village. Nine out of twenty-five children occupying this one room were attacked; but the epidemic did not extend to the other children of the school, occupying an adjoining room, nor did any of the little patients convey the disease to their parents, their brothers or their sisters.

The account, unfortunately, does not throw any light upon any probable cause for the outbreak, connected with the room in which the children stayed, which was well aired, had a morning and afternoon sun, and was simply a little damp.

Correspondence.

DONDERS MEMORIAL FUND.

BOSTON, January 1, 1888.

MR. EDITOR. — A Committee has been formed in the Netherlands in order to celebrate the seventieth birthday of an eminent man of science, Professor F. C. Donders, of Utrecht, on the 24th of May, 1888. On that date the law requires him to resign his duties as Professor at the University and as Director of the Physiological Laboratory, and it is now contemplated on that occasion to connect his name in a permanent way with the spot where he has lived and worked for more than forty years, by the creation of a fund, devoted to a scientific purpose, and which shall be known as the "Donders Memorial Fund." The rules and by-laws according to which this fund is to be governed as well as its more special destination will be drawn up and fixed with the concurrence of Professor Donders, and will be made to correspond most fully to his own wishes.

This Committee, which includes a large number of most distinguished citizens of the Netherlands, and many professors of the Universities of Amsterdam, Leyden, and Utrecht, have asked us to co-operate with them in honoring a name so well known, both in the field of biology and of ophthalmology.

We therefore kindly request you to bring this project to the consideration of those who you think might be willing to contribute towards the formation of the Donders Memorial Fund; and we shall be glad to receive and transmit to the Committee, with a list of the donors, any sums which you may send to us for this purpose.

HENRY W. WILLIAMS, M.D., 15 Arlington Street.

HASKET DERRY, M.D., 182 Marlborough Street.

Deaths reported 2,101: under five years of age 723; principal infectious diseases (small-pox, measles, diphtheria and croup, diarrhoeal diseases, whooping-cough, erysipelas and fevers) 338, acute lung diseases 322, consumption 281, diphtheria and croup, 167, scarlet fever 41, measles 32, typhoid fever 31, diarrhoeal diseases 29, malarial fever 10, puerperal fever 10, erysipelas seven, cerebro-spinal meningitis six, whooping-cough five. From typhoid fever, Philadelphia 11, New York six, Pittsburgh five, Boston three, Baltimore and Fitchburg two each, New Orleans and Lawrence one each. From diarrhoeal diseases, New Orleans 11, New York four, Philadelphia three, Boston, District of Columbia, Nashville and Fall River two each, Baltimore, Springfield and Holyoke one each. From malarial fever New Orleans six, New York four. From puerperal fever, New York, Baltimore, Pittsburgh, and Milwaukee two each, Boston and New Orleans one each. From erysipelas New York and Chelsea two each, Philadelphia, Boston and Milwaukee one each. From whooping-cough, New York, Philadelphia, Boston, Pittsburgh and Milwaukee one each.

In the 22 cities and greater towns of Massachusetts, with an

estimated population of 1,048,197, the total death-rate for the week was 23.12 against 20.18 and 21.14 for the previous two weeks.

In the 28 greater towns of England and Wales with an estimated population of 9,244,099, for the week ending December 17th, the death-rate was 22.1. Deaths reported 3,319; infants under one year of age 887; acute diseases of the respiratory organs (London) 413, scarlet fever 108, whooping-cough 157, measles 80, fever 54, diphtheria 47, diarrhoea 55, small-pox (Sheffield 17, Bristol and Preston one each), 19.

The death-rates ranged from 15.5 in Portsmouth to 35.7 in Blackburn; Birmingham 22.2; Bradford 17.9; Hull 22.0; Leeds 26.2; Leicester 21.5; Liverpool 20.6; London 20.1; Manchester 32.9; Newcastle-on-Tyne 26.2; Nottingham 27.9; Sheffield 21.9; Sunderland 22.0.

In Edinburgh 20.2; Glasgow 25.0; Dublin 38.7.

The meteorological record for the week ending December 31, in Boston, was as follows, according to observations furnished by Sergeant O. B. Cole, of the United States Signal Corps:—

Week ending Saturday, Dec. 31, 1887.	Barometer.	Thermometer.		Relative Humidity.		Direction of Wind.		Velocity of Wind.		State of Weather. ¹		Rainfall.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM DECEMBER 31, 1887, TO JANUARY 5, 1888.

CLEARY, P. J. A., major and surgeon. Granted leave of absence for one month. S. O. 138, Department of Arizona, December 25, 1887.

EBERT, R. G., captain and assistant surgeon. Ordered from Fort Custer, Montana, to Fort Pembina, Dakota Territory. S. O. 201, A. G. O., December 30, 1887.

EWING, C. B., first lieutenant and assistant surgeon. Granted one month's leave. S. O. 137, Department of the Missouri, December 27, 1887.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE UNITED STATES MARINE-HOSPITAL SERVICE, FOR THE TWO WEEKS ENDED DECEMBER 31, 1887.

BEVAN, A. D., passed assistant surgeon. Resignation accepted to take effect January 31, 1888, and leave of absence extended to that date. December 31, 1887.

BRAYTON, W. D., assistant surgeon. Granted leave of absence for thirty days. December 30, 1887.

SOCIETY NOTICES.

ALUMNI ASSOCIATION OF THE WOMAN'S HOSPITAL IN THE STATE OF NEW YORK.—Third annual meeting at the New York Academy of Medicine, January 18, 1888. Morning Session, 10 to 1: (1) Clinical Notes on Uterine Displacements, by Dr. G. A. Klebsch; (2) A Study on the Etiology of Prolapsus Vaginae et Uteri, by Dr. G. T. Harrison; (3) Septic Peritonitis following Laparotomy, by Dr. P. F. Chambers; (4) On the Etiology and Development of Caruncle, by Dr. J. G. Perry. Afternoon session, 3 to 5: (5) The Electrical Treatment of Fibromyomata, by Dr. A. H. Dockmaster; (6) The Use of Galvanism in Gynecology, by Dr. L. H. McGinnis; (7) The Use of the Tampon in the Treatment of Pelvic Inflammation, by Dr. T. A. Emmet. Dr. W. G. Wyllie will open the discussion of this paper on the affirmative side, Dr. J. B. Hunter on the negative. The profession are cordially invited to be present.

W. H. BAKER, M.D., Chairman.

H. C. COE, M.D., Secretary.

OBITUARY. ALONZO B. PALMER, M.D.

Alonzo B. Palmer, M.D., of Ann Arbor, Mich., professor of theory and practice of medicine, and dean of the faculty of the Medical Department of the University of Michigan, died December 23d, in the seventy-third year of his age. Dr. Palmer was a native of Richfield, Otsego County, N. Y., and obtained his education at the College of Physicians and Surgeons of the Western District of New York, from which he took his degree in 1839. He settled in Tecumseh, Mich., in 1850, but soon moved to Chicago, where in 1852 he became city physician. In the same year he was appointed professor of anatomy in the University of Michigan, where he afterward occupied successively the chairs of materia medica and therapeutics and of diseases of women and children, until his transfer in 1860 to the professorship which he held at his death. He was chairman of the section of pathology at the *International Medical Congress* last September.

Lecture.

THE HISTORY OF MEDICINE.

INTRODUCTORY LECTURE.¹

BY J. S. BILLINGS, M.D., LL.D. (HARY.) SURGEON, U. S. A.

THE power of belief, faith, imagination, or expectant attention to affect the material organism of the body is so well known that I need only give one or two illustrations. The first is one which I noted from the lips of the late Prof. Joseph Henry, Secretary of the Smithsonian Institution:

Some years ago, during the meeting of the Scientific Society in Cincinnati, a certain doctor called on Professor Henry and informed him that he had discovered that all the effects of a drug could be produced by holding it in the hand, and invited the Professor to witness the experiment. To this he agreed, provided he could bring a friend with him, which was assented to. At the appointed time, he went with Professor Agassiz to the doctor's house, where they found quite a number of persons assembled. They were taken into a room where there was a row of bottles containing powdered drugs, labelled opium, ipecac, rhubarb, Rochelle salt, etc., and were requested to put a portion of the powder from each of these bottles in pieces of paper provided for the purpose, to fold these and mark each with a number to designate the bottle from which it was taken, for their own private information.

Everything being arranged, they seated themselves in the parlor, and the Professor placed one of the paper packets in the hand of each of a number of persons present. He then walked up and down and discoursed on the certainty of this mode of medication, the great importance of the discovery, etc.

Presently one of the subjects of experiment began to complain of headache, another of nausea, a third of pain in the abdomen, a fourth of sleepiness, etc., and these symptoms continued to increase in strength. Turning to Professors Henry and Agassiz the doctor asked if they were satisfied, to which they replied that they were. He then requested a certificate to that effect, which they excused themselves from giving. The next day it leaked out that they had put nothing in the papers.

I may remark that the doctor was in error in supposing that his theory was new, for as long ago as 1746 a certain Privati at Venice recommended much the same method of administering remedies, especially in gout and paralysis. He called the method *intoxicatura*, and it consisted in enclosing the medicines in glass tubes which were to be electrified and then held in the hand.²

It is hardly necessary to occupy time in specifying the effects of mental states upon the body. Jaundice has been produced by anger, and also by grief. The sudden change of color in the hair from black to white under the influence of fear or sorrow is well authenticated. How often does it happen that a person suffering violent toothache finds his pain disappear as he enters the door of the dentist. Convulsions and epilepsy have been produced in children by fright, or by the milk of the mother changed by anger or fright. Finis and Charlot each relate cases of criminals condemned to death, and having their eyes bandaged pre-

paratory to the fatal stroke, who died before any bodily injury was inflicted upon them. All surgeons of large experience know how unfavorable a sign it is when a patient declares that he will not recover, and they may properly refuse to operate, except in cases of urgent necessity, where the patient has expressed such a belief. I remember vividly a case at the battle of Gettysburg. An officer of unusual bodily strength and activity, and in excellent health, received a wound in the hip. On examination it was found to be but a slight flesh wound. Nevertheless the patient was, from the first, much depressed in spirits, and declared that he should never recover, and the event proved that he was a true prophet, for he died on the fourth day. Careful examination showed that the wound was, as had been supposed, a slight one, and every organ in the body was apparently in a normal condition.

What is known as "homesickness," the "heimweh" of the Germans, is a well-recognized form of disease in recruits, which in some cases may prove fatal, either directly or by leading to suicide.

The great nerve centres for mental impressions and operations receive their stimuli from and are acted upon by three different channels. First, by the quality of the blood itself; second, by the relative amount of blood furnished to the whole or certain parts of the brain, which amount is, in a great degree, dependent upon the action of certain nerve centres at the base; and third, from the ganglia of the special senses, sight, hearing, smell, taste and touch. It is through these last channels that the medicine man of Africa and Australia administers much of his remedies. If he can by ceremonies, conjurations and jugglery make his patient believe that he has driven out the evil spirit, or killed the snake, or removed the insect which was the cause of his pain, in very many cases he has cured the pain, that is, he has substituted one set of ideas for another in the mind of the sufferer.

But if emotions can produce disease they can also sometimes cure it. Take the following instance reported by Dr. Paris.¹⁰

After the discovery of the powers of nitrous-oxide, Dr. Beddoes determined to try it in a case of paralysis, the administration of the gas being entrusted to Sir Humphrey Davy. Before giving the remedy he placed a small thermometer under the tongue of the patient to take the temperature in order to make future comparisons. The paralytic man, ignorant of the nature of the treatment about to be applied, but from the statements of Dr. Beddoes fully impressed with the certainty of its success, on feeling the thermometer under his tongue concluded the talisman was in full operation, and declared that he felt the effects of its influence throughout his whole body. Davy desired his patient to renew his visit, when the same ceremony was gone through with and repeated every day for a fortnight, the patient gradually improving and finally being dismissed as cured without the use of any further applications.

Dr. R. T. Coleman, Chief Surgeon Stonewall Division, C. S. A., reports a case of a man with chronic rheumatism who was almost helpless, and in whom the limbs had begun to atrophy. A shell burst under the wagon upon which he was sitting with marvellous and instantaneous effect, producing a complete, radical and permanent cure.¹¹

¹ To a course of eight lectures before the Lowell Institute of Boston. Delivered December 27, 1887. Concluded from page 21.

² Sprengel, Hist. de la Méd., T. V., p. 256.

¹⁰ Pharmacologia, p. 28.

¹¹ Richmond Journal, 1872.

Dr. Manson¹² reports a case of a girl aged two years and three months frightened by a boy in a red mask, producing great terror, profuse perspiration, followed in thirty-six hours by convulsions, and death in the second week. The brain was found highly congested, but no other local lesions.

The mechanism by which sudden death is produced by fear is probably by prolonged syncope—that is, by stoppage of the action of the heart. Several cases are on record where the fear of a surgical operation has produced death. An educated man, sixty-two years old, being placed on the table for the operation of lithotomy, died a few seconds before anything was done.¹³

"A very intelligent officer¹⁴ had suffered for some years from violent attacks of cramps in the stomach. He had tried almost all the remedies usually recommended for the relief of this distressing affection, and for a short period the tris-nitrate of bismuth had been attended with the best results. The attacks came on about once in three weeks, or from that to a month, unless when any unusual exposure brought them on more frequently. As bismuth had been so useful it of course was continued, but it soon lost its effect. Sedatives were again resorted to, but the relief afforded by these was only partial, while their effect on the general system was evidently very prejudicial. On one occasion while greatly suffering from the effect of some preparation of opium given for these spasms he was told that on his next attack he would be put under a medicine which was generally believed to be most effective, but which was rarely used in consequence of its dangerous qualities; but that, notwithstanding these, it would be tried provided he gave his consent. This he did willingly. Accordingly on the first attack after this a powder, containing four grains of *ground biscuit*, was administered every seven minutes, while the greatest anxiety was expressed (within the hearing of the patient) lest too much should be given. The fourth dose caused an entire cessation of pain. Half-drachm doses of bismuth had never procured the same relief in less than three hours. For four successive times did the same kind of attack recur, and four times was it met by the same remedy, and with like success. After this my patient was ordered to join another ship on a different station."

No better illustration of the use which may be made of belief as a remedial agent can probably be adduced than is given in the history of Perkinsism. Dr. Elisha Perkins was a Connecticut physician, born in 1749. The discoveries of Galvani attracted his attention, although he did not understand them. In 1796, he announced the discovery of a means for the cure of pain, inflammation, rheumatism, etc., by the application of pieces of metal, known as the metallic tractors. These tractors consisted of a pair of pointed rods, the one of brass, the other of iron or zinc, which were to be drawn over the affected parts. These tractors were patented, and sold for five guineas a pair. For about eight years the fame of these increased amazingly; they were used in the public hospital at Copenhagen, and extensively in England, where there was a Perkinian Society, and pamphlets on them multiplied. They were favorite instruments with the

clergy, who, with women, are the best believers. To-day the whole thing is forgotten, and very few now living have ever seen a pair of the tractors.

A very good account of the methods by which the supposed virtues of these tractors were disproved is given by Dr. John Haygarth in a pamphlet printed at Bath in 1800, "Of the Imagination, as a Cause and as a Cure for Diseases of the Body." All the effects alleged to have been produced by Dr. Perkins's instruments were produced with pieces of wood of the same shape.

It is doubtful whether there are now any new follies in the world, any forms of errors of observation, or of blunders of reasoning appearing in our days, which were not committed long ago; and, on the other hand, it is doubtful whether any phase or variety of belief, or of practice based on irrational belief, ever wholly and permanently disappears. We have a Perkinism in our days, but we call it metallothérapie.

Within a few months a distinguished French physician, M. Luys, has published a book with photographs to prove the possibility of inducing various emotions and sensations in a hypnotized girl by substances enclosed in glass tubes and held at a distance from the subject, which is almost identical in its general scope with some of the observations of Professor Henry referred to above.

Charms, which act on the mind of the person charmed, always have some effect; in incantations, commonly a mischievous one. Hearne, the traveller in North America, relates somewhere that, being solicited by an Indian to give him a charm against some enemy, and convinced of the harmless folly of such sorceries, he complied, and drew on a sheet of paper some circles, signs, and words. The Indian who received this took care that the doomed man should know it; he immediately sickened, and before long died. Hearne resolved to make no more magic papers.

Additional evidence in abundance, if it be needed, is to be found in the writings of Braid, Carpenter, Maudsley, Bain, and others, and in the accounts of modern miraculous cures, such as those of Prince Hohenlohe and of the Zouave Jacob.

The question as to how these effects are produced, is one of much interest.

It is generally admitted that the result of the grotesque dress, chants and invocations, threats and magic words, is to inspire in the patient a belief in the power and skill of the operator, and in the efficacy of the means which he employs; and when a thorough, undoubting, and unhesitating belief exists, which can be directed at pleasure, it may be used to influence the functions of the various organs of the body much more extensively and with greater power than is usually thought possible, and results may thus be obtained which, to the inexperienced, seem little short of miraculous. We conclude that the essential agent is the belief itself, for the reason that it seems to make little difference as to what particular amulet, ceremony, or remedy is used.

What, then, is this mental condition which we call belief, and how is it possible that it should influence the various organs of the body?

As Mill remarks: "To determine what it is that happens in the case of assent or dissent, besides putting the two ideas together, is one of the most intricate of

¹² *Lancet*, Lond., 1846, II, p. 552.

¹³ See case in *Bulletin Médical*, 1873, III, p. 175, by Dr. Cazenave.

¹⁴ From illustrations of the *Via Velatrix*, etc., by a naval officer in the *Brit. and Foreign Med. Rev.*, Lond., 1817, Vol. XXIII, p. 567.

metaphysical problems." This difficulty is increased by the various senses in which words are used, and this word "belief" is a notable instance, being sometimes used as synonymous with knowledge, sometimes as opposed to it. Hamilton defines it as "that state of mind which is preliminary to knowledge"; that is, in which an unproved statement is accepted; but when it causes or relieves pain or paralysis, it is evident that we have something more than a mere assent to a proposition. The same applies to Fiske's attempt at explanation. He says¹⁵ that: "By a singular freak of language, we use the word belief to designate both the least persistent and the most persistent coherents among our states of consciousness, to describe our state of mind with reference both to those propositions of the truth of which we are least certain, and to the truth of those of which we are most certain. We apply it to states of mind which have nothing in common, except that they cannot be justified by a chain of logical proofs. For example, you believe that all crows are black; but, being unable to furnish a logical demonstration of the proposition, you say that you believe it, not that you know it. You also believe in your own personal existence, of which, however, you can furnish no logical demonstration, simply because it is an ultimate fact in your consciousness, which underlies and precedes all demonstration."

Neither of these apply to the state of mind which we are considering; namely, belief, with expectation, the strength of which is "often in an inverse ratio to the believer's experience and knowledge."

If we accept the definition, that "expectation is a highly representative experience," which is based on the supposition that knowledge and belief are essentially the same, except that the first is presentative, and the second representative cognition,¹⁶ we have probably come as near to expressing what is meant as is possible from the metaphysical side.

Let us see if we cannot make it a little plainer from another point of view:

Phenomena such as those observed by Professor Henry are accepted by some as ultimate and unexplainable facts; by others, as proving the existence of a special force in the human economy, from which, as we shall see, several medical systems have been deduced. That we may be able to judge of these speculations from the latest standpoint, let us consider the explanation of these phenomena which would probably be given by some physiologists of the present day.

With progress in our knowledge of the structure and functions of the nervous system, there has developed an increasing tendency to lay stress upon the possible or probable importance and frequency of the part which it plays in the causation of some diseases, and in the production of many of the phenomena of others. Insanity and other so-called diseases of the mind are now generally admitted to be due to disease or malformation of the brain; while that the nervous system has much to do with the production of fever, inflammation, skin diseases, etc., is becoming more and more evident. It is probable that each organ of the body is connected with certain parts of the brain. "and the ancient localization of certain emotions in certain viscera, though crude, is not without some

foundation in positive physiological facts. Morbid states of the viscera or of the centres of organic sensations may give rise to hypochondriasis or melancholia; and just as an irritated stomach may produce a headache, so the melancholic individual projects the obscure feelings in some definite objective form as the cause of his sufferings. He imagines that his vitals are being gnawed at by some hideous animal, or that his body is the scene of demoniacal revels. The special form of the hallucination will vary with the individual and his education; but it always takes some dread or malignant shape."

Now this nervous system, consisting of the brain, spinal cord and ganglions, with communicating cords or nerves passing between themselves, and also connected with all parts of the body, is pivoted, as it were, about certain small masses of gray matter which lie at the base of the brain. Above these are the centres connected with the special senses of vision, audition, etc., and also those connected with mental operations and consciousness; while below and behind are those which preside over the functions of organic life. The influence which the lower nerve centres exercise over the upper, has been known, and the reverse influence is equally important. One of the most common of nervous phenomena is a chill. This chill may be produced by a change in the blood which circulates through the nerve centres, as in the commencement of yellow fever or typhus, or by an impression made on the external branches of the nerves supplying the cutaneous surface of the body, as by cold, or by a change in the thin gray layer of the surface of the cerebrum or upper brain, which change is brought about through the channels of special sensation of sight, hearing, smell or touch. This last species of chill is not produced by the direct action of the centre of the sensory nerve upon the vaso-motor centre. If a man goes into a dark room and puts his hand by accident upon something cold, that is, of the temperature of the air, it will, in most cases, affect him but little. But if the room is strange, and the surrounding circumstances suspicious, and a slight motion of his hand shows that the cold object is a man's face, he will very probably have a slight chill. In this last case what has happened? The idea or mental picture of a dead man has been produced in the cerebral centres, and these have acted on the medulla and pons varolii, which again through the vaso-motor nerves, have caused a sudden contraction of the bloodvessels, producing in its turn disordered action of the heart, muscular tremors, and a sensation of general coldness. Observe that it is the conception, the imaginary picture, that has produced this. The cold face felt may have been of marble, or a wax mask; the result would have been the same so long as the man does not know the difference.

It appears, then, that the cold touch acted by evoking a mental image which may have been a very complex one. I might multiply illustrations, such as the production of nausea by the sight of a bleeding wound, of perspiration and purgation by fear, of rapid respiration and action of the heart by music or eloquence, or even by a vivid and life-like painting, of some of which effects almost every one has had experience.

Sometimes there are unusual connections between these ganglia, and then we have very curious phenomena of sensation or motion. We may, for example,

¹⁵ Outlines of Cosmic Philosophy, Boston, 1876, I, p. 61.

¹⁶ Thomson, (D. G.). Knowledge and Belief in Mind, July, 1877, p. 326.

¹⁷ Ferrier. The Functions of the Brain, p. 261.

have what is known as colored hearing, in which certain tones produce a sensation of color, so that the voice of one person gives rise to the sensation of red of another green, etc. If several of the ganglia are irritated at once we may have a result such as was produced in an epileptic, who said that he always knew when a fit was coming on by a smell of green thunder which he perceived. After his death it was found that there was disease involving the central roots of the nerves of hearing, smell and vision.

I do not assert that this explanation is correct, nor that it would be accepted by all modern physiologists; my purpose is not so much to discuss its merits as to point it out as a contrast to what I shall say hereafter.

It is possible that some of you may not, at first, see any special connection between this rather long and tedious account of the mummeries of savage medicine men and of the effects of what is called imagination; and the history of medicine, properly so-called, or the question of medical education, and yet I can assure you that it is of great importance to fully appreciate the power of which I have been speaking. It complicates almost every step in practical medicine, and especially all attempts to estimate the true power of remedies; it has given rise to more error and imposture, and has been, and still is, a greater hindrance to scientific medicine than perhaps anything else.

When attention is called to it, men are content to say that no doubt half of our diseases are imaginary, and can be removed by imaginary remedies, as if this were the whole matter. But when we speak of the power of imagination, or of the mind, or soul, on the body, we are greatly deceived if we suppose that we have explained anything, or that we have done more than merely to attach a name to the phenomena observed. We are using words as if they referred to definite cognizable entities, when, in fact, such is not the case. What definite idea can be gained from such phrases as a morbid imagination, a diseased mind, or the power of faith as a means of cure?

These may be, and in fact usually are, put aside as metaphysical and philosophical speculations, with which the physician has no practical concern; but this is a very great mistake.

The laws of life can only be known through the phenomena of mind, the laws of mental phenomena can only be studied through those of life, of life in abnormal as well as in normal conditions. Almost every day of his life the physician has to take into account mental peculiarities, if he does not degenerate into utter routine and formalism, and therefore it seems to me that a part of his education should consist in learning something about them. Those who condemn and depreciate metaphysics and philosophy, as unpractical and useless studies for a physician, will in the next breath tell you that a successful doctor must be a good judge of human nature. How is it then that one should acquire this judgment if not by the study of the phenomena of human nature, which I suppose to mean mental phenomena. It is perfectly true that the great majority of works on mental science are of little use or interest to the medical man, because they have no physiological basis; but this simply proves a defect in the method of study, and not the worthlessness or unimportance of the subject. It is not all a question as to whether the physician should philosophize,—that he must do,—the only question is, as to whether he shall do it well or ill.

But if the production of certain mental states, through impressions on the special senses of hearing, smell, sight, etc., can be used to modify the actions of certain organs of the body, and thus become an agent for the cure of certain diseases, and if this fact has long been known, you will naturally ask "Why is it that more use has not been made of it by educated and conscientious physicians?" As the Rev. Oswald Cockayne puts it:¹⁸

"From the cradle, modern Englishmen are taught to fight an angry battle against superstition, and they treat a talisman or a charm with some disdain and much contempt. But let us reflect that these playthings tended to quiet and reassure the patient, to calm his temper and soothe his nerves; objects which, if we are not misinformed, the best practitioners of our own day willingly obtain by such means as are left them. Whether a wise physician will deprive a humble patient of his roll of magic words, or take from his neck the fairy stone, I do not know; but this is certain, that the Christian Church of that early day, and the medical science of the empire by no means refused the employment of these arts of healing, these balms of superstitious origin. The reader may enjoy his laugh at such devices, but let him remember that dread of death and wakeful anxiety must be hushed by some means, for they are very unfriendly to recovery from disease."

The answer to this in brief is that these influences have been found to be much more powerful for evil than for good, that in ninety-nine cases out of a hundred their employment as a remedy will be either useless or will injure the patient, that when they succeed they tend to produce in others the morbid condition which they relieve in a few, and that their employment almost inevitably tends to the physical, mental, and moral deterioration of the person who tries to use them. Why, and how, this is the case, cannot be discussed here, but I will remind you that the answer is hinted at in Robert Browning's poem "Mr. Sludge, the Medium."

The moral of all this is, first, that no opinion as to the causes of disease, the effects of remedies, or the truth and value of so-called systems and theories of medicine can be made on a scientific foundation, unless the power and influence of belief, imagination, mind, brain, whatever you choose to call it, have been, by careful and repeated observations and experiments, eliminated as possible factors in the result which is to be judged; and, second, that it seems probable that mental phenomena, of the well and of the sick, should be a subject of study by the physician, and that this should be remembered in planning a course of instruction for medical men.

—The veterinary's life has its drawbacks. A student, having been sent to administer a dose to a sick horse, was asked by his preceptor what success he met with. "None at all," he replied, "the horse bit me." The preceptor then explained that he should have put the powder into a medicine-tube, and, placing one end in the side of the horse's mouth, blow it into his throat; whereupon the student proceeded to act upon the suggestion. Returning again, he was asked what success he had this time. "None at all," he answered, "the horse blew first!"

Address.

PROFESSIONAL REMINISCENCES.¹

BY BENJAMIN EDDY COTTING, M.D., ETC.

At Naples I was present at the daily evening deposit in one of the three hundred and sixty-six pits in the Campo Santo, the all-gathering receptacle of the city's dead poor. After a look into Herculaneum, a walk about Pompeii, and an ascent of Vesuvius, then active on its sides and not very indolent on top, we went on, stopping a few hours at Messina and Malta, to the Piræus; and thence to Athens by the *Sheke makra*, or at least where they should be.

At Athens I was under the special charge of Dr. Roeser, the Queen's personal and household physician, who was ever at hand and constant in his attentions. He took me to the Royal Medical Society, where I was called upon to talk of ether and chloroform, and other subjects of interest at the time. A few days later the venerable Rev. Dr. Hill told me that my "assistance" and remarks had been very kindly received at the Society, which proposed to make me a corresponding member, and that the diploma would probably reach America before we did.

One day there was a sham-fight, and the taking of a fortified place just out of town, in which all the available troops were engaged for sake of practice. This was led by the King and Queen, the Queen riding at the head of the attacking party. An officer of high rank, injured by his horse's fall into a pit, was brought to a tent adjoining the King's pavilion. Having been taken there by Dr. Roeser to the injured man, surrounded by their Majesties and high army surgeons, I was requested, at the Queen's intimation, to make an examination of the case. I did this and made a report, which, corresponding to the diagnosis already made, seemed to give general satisfaction. I then went with Dr. Roeser to the officer's home to announce to his wife and family his condition, and to prepare for his reception.

At Athens I had several Greek patients, also through Dr. Roeser. One of these, a peculiarly sad-looking young girl in typhoid fever, seemed very much pleased with my attendance. As, at my suggestion, Dr. Roeser omitted medicine for a day or two, the family were subsequently inclined to attribute to me her restoration to safety and health. . . .

At Vienna I went through the usual rounds, wondering, as I went, how careful and painstaking for science, "how careless of a single life." I once saw there an eminent diagnostician literally almost turn a man inside out for a slight external ailment—examining every organ, cavity, and function, *ad absurdum*; till I could not help saying, as an old neighbor said to me of another's practice: "I would rather trust old dame Natur unaided, and let disease have its own way," than undergo such a diagnostic preliminary investigation. . . . Omitting many things—I must not forget the supremely cordial attentions from Dr. John Brown, of Edinburgh. Never was a kindlier reception afforded any one. "Auld Reekie" and New Town, and all in and about that, he would have us

see and know; and his delightful talks made the visit most charming. He has recorded my call on him, in his own quaint way, in "Spare Hours; Second Series," page 328:

"I was greatly pleased when Dr. Cotting, of Roxbury, came in yesterday and introduced himself to me by asking, 'Where is Dick?' To think of our Dick being known in Massachusetts!"

Nor must I omit mention of my very pleasant call on the veteran, Dr. Stokes, at Dublin, and my visit to Meath Hospital. If the full allowance to the forlorn mortals there could be called "feedings," the wonder was what low diet would be. Meagre soups or broths may possibly be high living for poor wretches who naturally, as a professor once said to me, "never see a bit of meat from one year's end to another."

Losing my way in Dublin, I asked a trig and trim policeman the direction of St. Stevens Green. "Co," said he, "right square round, to the left, and you'll soon find it after mätting (meeting) you." Pretty well for a native! . . .

In 1863, when in Brazil for other purposes, I visited hospitals in various places. The principal, Casa Misericórdia, at Rio de Janeiro, especially in its newer portions, was a model. Its wards were arranged around pleasant and shaded court-yards, delightful to those in bed, as well as to the convalescents resorting to them. It was notable, also, for its high ceilings, with windows from the floor upwards; for absolute cleanliness; for the pleasing arrangement of its white-covered beds, with their red blankets rolled into cylinders at the foot-board. The medical attendants seemed fully posted in all the latest science of the day, and were very considerate to the sick in their charge.

The Dom Pedro II Hospital for the Insane, at Botafoga, is worthy of all praise. Our first visit there is fully described by Mrs. Agassiz in her "Journey in Brazil," pp. 80-81, where also a picture-page gives a very good idea of its situation and the surrounding scenery.

The Brazilians were then at war with Paraguay, and the Emperor, ever on the lookout for medical, as well as other scientific matters, called me to his palace to discuss with him anaesthetics and other methods of care for sick and wounded soldiers in the field, naturally supposing that our long Civil War had taught something in such matters. Recollections of these discussions undoubtedly led His Majesty, when in Boston, eleven years afterwards, to name me one of the seven he asked to breakfast with him. With this in mind, also, he was induced to wait over a day in order to attend the annual meeting of the Massachusetts Medical Society, and, contrary to his usual wont, to accept honorary membership in the Society.

And here I may be permitted to introduce an anecdote of my friend, the late Dr. Wucherer, of Bahia,—an extraordinary linguistic scholar and learned physician:

When the yellow fever raged in Bahia (a few years before I was there), to aid helpless sufferers and to quiet the people, Dr. Wucherer took yellow-fever patients into his house, and filled his grounds with booths and tents for those who could not find other shelter. For all this nobody thanked him; but some called him foolish for so doing.

A few seasons afterwards, an Austrian ship-of-war anchored in the harbor. A sailor, on shore by permit,

¹ Read, in part, before the Norfolk District Medical Society, October 25, 1887. Continued from page 25.

The *London Lancet* of December 31, 1887, received here since the last number of this Journal, in a review of the past year, says, "Both the spray and the gauze of the Listerian method are now rarely seen. That this is a gain who can doubt?"

became ill, and the ship's surgeon having named the disease yellow fever, Wucherer was called in consultation as an expert. He found the surgeon in error, but, to save him from disgrace, allowed the name to stand, and kept the patient under treatment and isolated until after the ship sailed. The surgeon was commended for his prudence, and Wucherer for his skilful services.

Months afterwards, when the affair had entirely passed from his mind, Dr. Wucherer was summoned from a social medical meeting by an official, to receive into his own hands the heavily-sealed credentials of Knighthood from the Austrian Government! The ship's captain had reported him as having probably saved the ship's crew from the dreadful disease.

He was accustomed, facetiously, to say of the whole affair, that "for serving the sick and the public at the supposed risk of his family and himself he got nothing but reproaches, but, for acting out a fractional white lie, he was knighted!"

Returning to America from Brazil by way of Europe, then the only direct way, I visited the great hospital of San José in Lisbon, where the ship made a stop for supplies, etc. I saw there, among other curiosities, an apparatus for the prevention of ante-mortem burials—a series of rings for the fingers and other attachments, operating, on the least motion, upon bells in a guard-room near by. Only once had an alarm been given, and then in a doubtful case, wherein death was indubitable on the following day.

On the evening of December 31, 1839, I attended the opening of the Lowell Institute of Boston, "assisting" Dr. Jeffries Wyman, its curator. In like manner, and for like purpose, I often went to the lectures. One season, I had the full charge during my friend's absence abroad. On his resignation in 1843, I received an appointment to the position which he had vacated. It has been a good thing for me in many ways—not the least in saving me from becoming a stereotyped example of my profession. No stranger—and I have met with many—ever, to my knowledge, "set me down" as a doctor of medicine from characteristic manner or conversation. One often needs a stimulus to keep him out of the ruts of his calling; "bayonets behind him," as an eminent lecturer said to me not long since, "to drive him out of routine tendencies." Besides, it gave me some acquaintances of inestimable value. To it I owe the ever-continued and confiding friendship of the late Prof. Louis Agassiz. He always, to the last, made my house his resort for rest from the labors and anxieties of his multifarious enterprises and schemes. He, with Dr. A. A. Gould, gave my home its name, and always manifested great affection for it and its inmates.

In 1847, I was elected a fellow of the American Academy of Arts and Sciences, a further evidence of the affectionate regard of Drs. Hayward and A. A. Gould, and Professor Agassiz.

On retiring from its council by legal limitation I started a subscription, which resulted in a liberal fund for printing the Academy's papers, "a good plant springing from the seed you sowed," said, in a recent note to me, the treasurer, in office at that time. In presenting my offering to start a project which had for a time been ineffectually talked of, I merely added that I felt it to be the most valuable paper it was possible for me to offer the Academy for the advancement of science.

One day, in the earlier months of my practice, a vagrant near by my office, despairing of being of any further use to the community, swallowed nearly two ounces of arsenic, and I was called to smooth his way out of the world. The affair becoming somewhat notorious, the then editor of the *Boston Medical and Surgical Journal* called on me for notes of the case. He was ever on the alert for remarkable cases, and I could not resist his persistent importunities.² This was the beginning and the cause, on the principle that one good turn deserves another, of a multitude of articles and scraps which editors of the *JOURNAL* have subsequently from time to time drawn from me to fill up with when other practitioners, older and abler and more experienced, had declined. Every thoughtful and progressive practitioner necessarily wishes to keep himself informed of the improvements in the science and art of his calling, and to know how others are treating disease. This can be done only through periodical publications, wherein for such purpose each should feel bound to contribute his portion to the general stock. The usual plea that one has not anything of interest or value amounts to nothing. Even the most trivial case may unexpectedly prove of importance. The immature report of the case just alluded to became the basis of a solid argument in a capital trial not many years afterwards.

One of my papers had unusual sequences—mind I do not say consequences. In 1852 the reader for the annual meeting of the Norfolk District Society failed near the last moment, and I was "pressed" in to supply his place. The paper which was then read the Society voted to print. I resisted; but after six months' importunities surrendered it to the secretary. He published it in the *Medical Journal*. Some time afterwards the then venerated Nestor of the profession addressed me with some friendly criticisms, and, in conclusion, remarked: "Well, I shall have to write you young men a letter." His "*Letters to a Young Physician*" followed. While this volume was in preparation another professor, getting a little the start, issued a collection of papers under the title of "*Nature in Disease*." This happened by chance to be the title of my own paper above referred to, published two years previously. He came to me with the proof sheets and asked me to write a notice of his book for the *Medical Journal*. I did so, and had the satisfaction of hearing myself accused of playing "toady" to a great man.

A copy of this book having been sent to Sir John Forbes, then writing on similar subjects, Sir John called his next publication, "*Nature and Art in the Cure of Disease*," avowedly based on the title of the book sent to him. Not long afterwards a third professor called at my house, and, after alluding to the other professors' publications, and adding that he, too, probably had loose papers enough to make a similar volume, produced a big bundle and asked me to arrange, edit, and publish the same! This cost me midnight oil for a number of winter weeks thereafter. The work appeared with the title of "*Surgical Reports*," and I wrote a notice for this also, by request.

I may add further that on the appearance of Sir John Forbes's volume, Dr. Jacob Bigelow asked me to collect, edit, and publish with him a series of suitable medical books and papers, the series to be entitled "*Rational Medicine*," and the first volume to be a re-

² See Boston M. and S. Journal March 7, 1834, p. 78.

publication of Forbes. Dr. Bigelow wrote a preface for the series, and I gathered together documents for the second volume. A publisher had already begun his part when a reprint of Sir John Forbes's book appeared in New York and killed the scheme. Dr. Bigelow's preface was afterwards published in his "*Modern Inquiries*," p. 245, where also may be found a list of my collection, with one addition, which Dr. Bigelow insisted on including in the number.

A rather unusual concurrence of sequences this after all.

Thus it was that I happened at first to be called upon to contribute to the *Boston Medical and Surgical Journal*. Thus it was that I became interested in its welfare, and was induced to help fill it up when others did not. In later times the demands for "copy" became quite frequent. In 1872 the editor was taken very ill and obliged at last to give up his charge. The case seemed desperate, and I was requested by the assistant³ to "lend a hand." After months of continued exertion with his able aid a new interest was awakened, especially in the younger men. The present plan was adopted, and more than thirty medical men (including the editor and his assistants), were secured as regular collaborators, and put in responsible positions in its service. Moreover, the JOURNAL was purchased of the printer,⁴ who had owned it for many years, and placed in the hands of the profession. All this of course cost time, labor, and thousands of dollars, cheerfully bestowed without a farthing's return to those who contributed, except the abundant satisfaction of seeing a prosperous medical journal in the possession of the profession, solely for their use, wholly independent of external or trade influences.

It seems to have been fated that I should have more than an ordinary share in "mending" the fortunes of Medical Societies.

In 1842, I was asked to become the President and revive the Boylston Medical Society of Harvard University, a Students' Society, but having a young graduate for its chief officer. For several years it had been dead, buried, and apparently passed resurrection. Taking five or six students into confidence and telling them my plans, we formed a governing board, and announced by a large printed placard a meeting of the Society. This done, inquiries of its nature and objects soon became frequent. Meanwhile (all the Society's previous records and regulations having been irretrievably lost), we had adopted by-laws, and began to admit members, on condition that they would take active part in its exercises and pay an entrance fee. Thus membership soon became a privilege and a distinction. Good work was done, and the College year ended with a full and active Society of over forty members. The same plans have been continued, with like success to the present time.

I was sought out and called to preside at the first meeting for the formation of the Obstetrical Society of Boston; and afterwards when, in the commotion of war time and from other causes, it seemed about to expire, I then, with a member, now years ago gathered to his fathers, arranged the plan by which it has enjoyed unusual prosperity ever since. Any one interested may find a full account in the Historical Sketch prepared and printed for that Society.

In 1855, on the lamented death of my class-mate, Parkman, I was chosen to his place as recording-secretary of the Massachusetts Medical Society. How this could happen greatly disturbed some of my professional neighbors who, I hope, were satisfied when they were told, by one of the gentlemen himself, that two of them had proposed my election without consulting me, and without any knowledge on my part of their purpose. I was continued in the office and that of corresponding secretary for more than eight years. Among other labors I prepared a Digest of the State Laws relating to the Society, and suggested and carried through a number of its more important By-Laws; notably one on ethics, by which all personal matters, and matters of discipline, are at once removed from public meetings, and relegated to a standing committee, to be dealt with according to merit—in private. I also prepared the "Annual Discourse" read to the Society in 1865, which created unusual discussions and criticism; and I had thought with that my duties done, and my course finished with the Society.

But when, some years later, the Society was in need of renovation and awakening, I was asked, at whose suggestion I never knew, to assist with others, in restoring its former prestige, and in placing it on its present prosperous course. It was a laudable project and was supported by the best men in the profession all over the State. But it required much labor, and not a little self-sacrifice. What was done is well known to the profession. I trust that I did my share of the work. Many disinterested fellows were personally engaged in the matter, and the results seemed to gratify the well-wishers of the Society. . . .

Thus the State Society, now on its renovated career, is a power for good to the profession, unsurpassed by any institution of the kind in the land. Its membership gives to the community also the surest evidence it can have that the aspirant for practice is a *Regular Physician*—a *happy term*, a truly fortunate one, as it indicates that its possessor has taken in preparation the *regular* established course, approved from all time; that he is thoroughly loyal to professional obligations; that he continues *regular* in following with assiduity every laudable means to acquire, from every and all sources, any and everything that will conduce to the good of the sick, and the advancement of his Science and Art, untrammelled by dogmas, unrestrained by sects, and not bound to any "exclusive or irregular system"; not fearing to heed the dicta of nurses when apt and fitting, or the "sayings" of old women—willing even *ab hoste doceri*.

To this large and influential Society, now numbering over sixteen hundred members, and ever increasing, the profession, and the individuals composing it, may look for adequate support, and a high position which not all the laws of legislatures can insure, and not all the machinations of detractors and charlatans can take away.

(To be continued.)

—Sir Andrew Clark, of London, is quoted as saying: "I worked twelve years for bread, twelve for butter, and twelve more for the luxuries of life."

—In the *Edinboro' Medical Journal* for January, 1888, Mr. B. Langley Mills, surgeon of the medical staff, Bengal, reports the death of a non-commissioned officer from hydrophobia one year and nine months after being bitten by a tame monkey.

OXALURIA.

BY F. W. ELLIS, M.D., OF SPRINGFIELD, MASS.

By oxaluria we mean the presence of oxalate of lime in the urine. It is not a disease—it is, at most, only an expression or symptom of disease. It is doubtful if we are justified in considering the presence of a slight amount of calcic oxalate in the urine as abnormal. Traces of its presence in urinary sediments from individuals in apparently excellent health are very frequently met with. In some instances, the oxalic acid may be ingested in the vegetable food taken, for oxalic acid and the oxalates are found in very many plants. It is not likely, however, that these cases of slight oxaluria are always due to this cause. Every practitioner who has occasion to make frequent microscopic examination of the urine must be impressed with the number and variety of the cases in which calcic oxalate is encountered in this secretion. This frequency of occurrence tends to make us underestimate the importance of the subject. When we reflect upon the importance of the chapter in medicine and surgery devoted to urinary calculi, and when we recall the fact that one of the most frequent, and certainly the most dreaded, constituent of the calculi is calcic oxalate, nothing further is needed to indicate the interest that every physician should take in the subject of oxaluria. The calcic oxalate, or mulberry calculi, is harder than the other varieties, and, consequently, is the most difficult to crush and remove by litholapaxy. It is apt to be rough, and, as a result of this irregularity of surface, excite a great amount of irritation. Even when it does not form the main substance of the concretion, it often serves as the nucleus and starting point of others. For these reasons, every fact that tends to enlarge our knowledge of the mode of origin of calcic oxalate in the economy, and the causes of its deposition in the urinary tract, must be a desirable addition to medical science. Regarding the subject from this standpoint, no practitioner can question its importance.

There is, however, great diversity of opinion as to the diagnostic significance of calcic oxalate deposits in the urine. Since the first recognition of this substance as a urinary constituent, numerous contradictory statements have been made regarding the significance of such an occurrence. After an attentive perusal of the literature of the subject, and a careful consideration of the various theories advocated to explain the origin of the oxalic acid, one cannot escape the impression that something essential to the successful elucidation of the question has been overlooked, or has not yet claimed sufficient attention.

One of the mistakes generally made is that of regarding oxaluria as a disease, and not as a symptom. Oxaluria, like albuminuria, is a symptom. The causes of albuminuria are widely different in their character, and the same may be true of oxaluria. Hence, in seeking for an explanation for the appearance of oxalate of lime in the urine, we have no right to expect a single one applicable to every case.

In treating of oxaluria and oxalemia, it will be useful, at the outset, to consider some of the undisputed facts bearing upon the subject. First, we know that oxalic acid is a poison. Fatal cases of poisoning with this substance are not uncommon. The careful experi-

ments of Koch¹ demonstrate that the soluble oxalates paralyze the muscles, heart, and nervous system. A solution of neutral oxalate of ammonium injected beneath the skin of a frog caused fibrillary muscular contractions, and paralysis of the voluntary muscles and the heart. The lethal dose, for the frog, was found to be 12½ milligrams of the salt. Experiments upon warm-blooded animals gave quite similar results when the drug was injected subcutaneously.

Another well-ascertained point is, that a certain proportion of the oxalic acid or oxalates introduced into the body through the stomach or subcutaneously reappears in the urine under the form of calcic oxalate. In the experiments of Koch just mentioned, crystals of oxalate of lime were constantly found in the kidney, and in that organ alone. In cases of poisoning by the acid, a large amount of calcic oxalate crystals can be obtained from the urine.

These two facts having been determined; namely, that oxalic acid is a poison, and that it manifests its presence in the system by its elimination in the urine as calcic oxalate, are we justified in assuming from these premises that whoever voids oxalate of lime in the urine is being poisoned? The views of different writers upon this point are very discordant. No unequivocal answer can be given to the question until investigations have been made to determine the effects following the long-continued administration to animals of small doses of oxalic acid and the oxalates. I am not aware of any such experiments having been made. Another subject for experimental investigation is the action of solutions of *calcic oxalate* upon the physiological processes. I think that we have very little reason to expect, *a priori*, that solutions of calcic oxalate should not possess toxic properties. Ringer² has endeavored to show that the soluble oxalates arrest function by the withdrawal of lime from the tissues. He asserts that a lime salt must be present in the circulating fluid, to sustain the contractility of the cardiac muscle. He reports the following striking experiment: The detached ventricle of a frog's heart was enclosed in a Roy's "tonometer," and was supplied with an artificial blood mixture through a perfusion cannula. A small amount of a five per cent. solution of oxalate of ammonium was then added to the circulating mixture. The ventricular contractions immediately grew weaker, and contractility ceased in a few minutes. The nutrient fluid was then diluted, but the ventricle remained inactive. A small amount of a one per cent. solution of calcium chloride caused a speedy return of the spontaneous contractions.

Ringer reports another interesting experiment which will chiefly interest us: He prepared two solutions, one containing chloride of calcium, and the other oxalate of ammonium. The proportionate amount of these ingredients were such that equal quantities of the two solutions nearly neutralized each other, a slight excess of the lime salt remaining. Of course, the combination of these substances produces oxalate of lime. It was found that when quantities of the two solutions sufficient to just neutralize each other were added to the fluid supplied to a frog's ventricle, the cardiac contractions became weakened. A sufficient amount of the *oxalate of lime* must have been dissolved by the circulating fluid to poison the cardiac

¹ Wirkung der Oxalate. Archiv. f. exp. Path. und Phar., Bd. 14, s. 123.

² Practitioner, Vol. 34, p. 81.

muscle. Hence Ringer admits that oxalic acid exerts a direct poisonous action upon the muscle, and what he asserts of oxalic acid, in the light of this experiment, would seem to be true of calcic oxalate. Although these experiments need confirmation, and require to be supplemented by a variety of others performed upon warm-blooded, as well as cold-blooded animals, it does not appear that we have any theoretical reasons for doubting that considerable amounts of oxalate of lime circulating in the blood must have a deleterious action upon the functions of the body. It is true, the urine of persons in apparently good health may sometimes contain a relatively large amount of calcic oxalate sediment.

Roberts² states that "subjects of mulberry calculus, especially children, are often in the enjoyment of blooming health." As an offset to this assertion, however, we have the authority of Ultzmann⁴ that weakly and anæmic children are the ones that are particularly predisposed to oxalate of lime calculus. Chambers⁵ asserts that under-fed children living in the country often have oxalate of lime in the urine. According to my own experience, a copious sediment of oxalate of lime is not often found for a considerable period in the urine of persons in vigorous health. Its long-continued presence in this secretion is generally indicative that some of the functions of the individual are not being performed as they ought.

The oxalate is very insoluble in water. This property tends to render obscure the explanation of its mode of elimination from the system. The acid phosphate of sodium, which is ordinarily present in fresh, normal urine, has been found to have a solvent action upon the calcic oxalate. This would explain why the oxalate is held in solution in fresh urine, and its gradual deposition, as the acid phosphate becomes converted into the neutral phosphate, in consequence of chemical changes taking place in the urine. This explanation, however, does not account for the solution of the oxalate in the blood, from which the urine is secreted. It has been found that some other saline solutions have a slight solvent action on the oxalate. The oxalate, moreover, is not perfectly insoluble in water. Storer⁶ gives the solubility of calcic oxalate in water as 1-500000. It has been estimated that ten ounces of water are capable of dissolving 1,000,000 of the crystals. That the oxalate can be dissolved in the stomach, is proven by the fact that it reappears in the urine after the ingestion of foods containing it. There can be no doubt therefore, that the substance can be dissolved, or held in solution in the alimentary tract, blood and the urine; but the laws regulating its solution and deposition have yet to be discovered. Why it should be deposited in the kidney or bladder of one patient, and another, whose urine is loaded with it, should escape, demands further investigation to determine. And, of the many unsolved problems connected with the subject of oxaluria, this is perhaps the most important. When the laws governing its solution and precipitation within the body are made manifest, we may reasonably hope to be able to prevent the formation of calculi composed of it in oxaluric patients. There seems to be no doubt that mucus favors the crystallization of calcic oxalate; acting in this respect, very likely, like a foreign body. The

crystals are generally found in the urine intimately mixed with the cloud of mucus that slowly falls to the bottom of the receptacle. The starting-point of many calculi is probably formed by a clump of mucus that has occasioned the crystallization of oxalate of lime about it.

There can be no doubt that the larger portion of the oxalic acid excreted, is manufactured within the body. There have been those, however, who have disputed this. Owen Rees first elaborated the theory that oxalic acid is produced from the decomposition of uric acid outside the body. The discovery of oxalurate of ammonium in the urine by Schunck, lent some support to this theory. Oxaluric acid is a decomposition product of uric acid, and is easily converted into oxalic acid; hence it was inferred that uric acid transformed into oxaluric and then oxalic, was the source of oxaluria. Basham gives an excellent exposition of this theory of the causation of oxaluria, in Reynolds's "System of Medicine."⁷ He there affirms in a very dogmatic manner, and with very scanty evidence, that "oxalate of lime, as a sediment in the urine, is of no other significance than that of a lithic acid diathesis." An excess of oxalate of lime in the urine meant for him an excess of uric acid in the system. It is an easy matter to demolish this theory. In the first place one of the cardinal doctrines of Basham and his school, namely, that the oxalurate of ammonium of the urine is changed to oxalate, was disapproved by Neubauer.⁸ He found that in progressive decomposition of the urine, the oxalurate of ammonium is changed directly into carbonate of ammonium, and not into oxalic acid and urea. Oxalic acid has been found in the blood by Cantani and Garrod. This oxalæmia cannot be accounted for by Rees's theory. The explanation, according to this theory, of the origin of renal concretions of oxalate of lime, would be very difficult. It is exceedingly improbable that the decomposition of oxalurate of ammonium can take place almost instantaneously after the secretion of a urine of normal reaction and perfectly free from every trace of fermentation. Renal calculi of oxalate of lime, however, are very common.

This is abundantly proven by the experience of Cantani,⁹ who cites numerous instances. I have recently had under my own care a case of the kind. The gentleman had been a recent sufferer from renal colic, and had experienced several severe attacks. He had presumably been treated for lithuria. Upon examination of the urine I found it loaded with oxalate of lime. The patient had luckily saved a calculus of about the size of a pea, that he had passed through the urethra. I found this, upon analysis, to consist almost wholly of calcic oxalate. I never found any excess of uric acid in the urine. If the urine and the calculus had not been carefully analyzed, it would have been natural to have considered the case one of lithiasis, and to have treated it accordingly. Oxalate of lime is probably a much more common cause of renal colic than is generally supposed; and for this reason the urine of patients afflicted with this disease, should always be carefully examined. Oxalate of lime may be found, indicating the cause of the painful paroxysms.

⁹ Die Stoffwechselkrankheiten.

Another fact disapproving the theory of Rees, and one that may not be generally known by the medical profession, is that oxaluria is common among horses. Williams¹⁰ speaks of its occurrence in horses that are irregularly worked, like hunters, and those too abundantly fed with saccharine substances, as turnips and carrots. I have examined the urine of a number of horses and I have found oxalate of lime very frequently. In a stable containing five horses, I found abundant deposits of oxalate of lime in the urine of three of the inmates. In one instance the urine was literally loaded with it. The form of the crystals in this case was not the typical octahedral, but was a four-sided prism with pointed ends. This form is very rarely found in man, and might be easily mistaken for other crystalline constituents of the sediment, were not careful micro-chemical tests applied to reveal the true nature of the crystals. The horse excretes a large amount of hippuric acid, but very little uric. We have no reason to suspect that the decomposition of hippuric acid is a source of oxalic acid.

For these and other reasons the theory that the excreted oxalic acid is formed in the urine outside of the body cannot be sustained. We cannot affirm that oxalic acid is never formed during the decomposition of the urine, but we have abundant proof that this is not the ordinary cause of oxaluria.

Some of the other theories to account for the presence of oxalate of lime in the urine are more probable. A conservative *résumé* of these theories is given by Salkowski and Leube.¹¹ They all have the common defect, that while they may seem to be sufficient to explain the occurrence of oxaluria in some instances, they are entirely inadequate to do so in others.

The theory most commonly accepted is that the oxalic acid originates in defective metamorphosis within the body. Cantani is one of the ablest advocates of this theory. In his elaborate work upon the diseases of metamorphosis, he takes the ground that oxaluria is due to a condition akin to that of diabetes. He believes that the oxalic acid originates from the abnormal disintegration of the carbo-hydrates. There are many facts that lend probability to this view. The acid is very readily prepared in the chemical laboratory by the action of reagents upon sugar, starch, and cellulose. This fact would seem to render probable the possibility of its formation from the imperfect oxidation of these substances in the body. Cantani's mode of treatment for oxaluria is based upon this theory. He states that the condition is especially common in individuals indulging to excess in sweets and starchy foods. His treatment consists in very largely withdrawing these articles from the food and substituting an anti-diabetic diet. He claims to have permanently cured many patients in this way.

But we find other recognized authorities maintaining that oxaluria is the result of imperfect metamorphosis of nitrogenous substances. This was Beneke's theory. It has been found that oxalic acid cannot be made to wholly disappear from the urine of fasting animals. I have found calcic oxalate quite abundantly present in the urine of a patient subsisting entirely upon a moderate amount of milk-punch.

Tyson¹² advises that in the treatment of oxaluria

the patient be allowed only a moderate amount of nitrogenous food, and in bad cases no meat at all be permitted. It would be hard to explain the good effects of both Cantani's and Tyson's widely different modes of treatment upon the assumption that the theory of one alone is correct. Before endeavoring to reconcile the apparent incompatibilities existing in the views of these two authorities, it may be well to consider some of the other possible sources of oxalic acid in the body.

Various authors have endeavored to trace a connection between the formation of mucus and that of oxalic acid. Hoppe-Seyler¹³ states that the crystals of oxalate of lime are especially abundant in catarrh of the urinary passages, and of other mucous membranes. He also affirms that the connection between impaired respiration and the excretion of calcic oxalate has not been proven. Ralfe¹⁴ also accepts the possibility of the formation of oxalic acid from the decomposition of mucus, and gives considerable prominence to the theory. He states that crystals of oxalate of lime have been found in the mucus of the gall-bladder, and in the gravid uterus. Fürbringer also found them in the sputum of the diabetic. Ralfe is inclined to the view that the numerous oxalate of lime crystals found in the urine of patients suffering from spermatorrhœa are derived from the mucus of the genito-urinary passages. Ultzmann¹⁵ has remarked the frequent association of oxaluria and spermatorrhœa and urethral disease. He says that he has often caused the oxaluria to disappear by local treatment of the urethra. I myself, have had several cases of true spermatorrhœa associated with oxaluria. I also recall another interesting patient who was troubled with an obstinate prostatic disease whose urine was loaded with calcic oxalate. I have never, however, felt the necessity of attributing the oxalate of lime found in such cases to the presence of seminal fluid or mucus in the urine. The case that I have already mentioned of the gentleman that had suffered from a severe renal colic is sufficient to demonstrate that there is not necessarily any reason for attributing oxaluria to the presence of semen in the urine. In the many specimens of the urine of this patient that I examined I never failed to find a large number of spermatozoa. These specimens were passed at different times of the day, some of them during my visits. The formation of the oxalate of lime calculus in the kidney in this case showed that there could be no direct connection between the oxaluria and the spermatorrhœa. The crystals of the oxalate could be found very soon after the urine was passed, long before we could have any reason to suspect that any decomposition had taken place. The form of the crystals in this case was very suggestive. They were apt to be small and of irregular form, resembling those obtained by immediate precipitation upon the addition of a solution of oxalic acid to one of calcium chloride. They seemed to denote that the urine was surcharged with the oxalate and that many of the crystals were formed almost instantly after the secretion or excretion of the urine.

Although such cases as the above do not support the theory of the formation of oxalic acid from mucus, there are certain facts that render probable the possi-

¹⁵ Die Harnsoneramente.

bility of such an event. It has been found by Landwehr and by Hammarsten¹⁶ that a decomposition product can be obtained from mucin having the properties of a carbo-hydrate. The further decomposition of this carbo-hydrate, which Landwehr calls animal gum (*thierische Gummi*) might yield oxalic acid. Behrens¹⁷ calls attention to the frequency with which calcic oxalate is found in the vicinity of, or even in, slime-bearing cells of plants. Although it may not be fair to compare the slime of plants with the mucus of animals, there are points of similarity in some of the physical properties of the two substances. Plant slime, moreover, readily yields oxalic acid when treated with nitric acid.

I think that, perhaps, I have already dwelt too long upon the conflicting theories that have been advanced to account for the formation of oxalic acid in the body. I can only briefly allude to others. The theory of increased oxidation has been advocated to explain certain cases. The objections to the general application of the theory of impaired oxidation would apply to this one. Theoretically, perhaps, increased oxidation and metabolism with the formation of incomplete products, would explain some cases of oxaluria, but in default of experimental and clinical proof of the correctness of the hypothesis, we cannot profitably discuss it here.

Among all the multitude of diseases and conditions in which oxaluria has been found there is one symptom or condition, and perhaps only one, that has been very constantly met with, namely indigestion. The frequent occurrence of dyspepsia and all the symptoms usually accompanying it with oxaluria has been often noticed by various writers. Some have been inclined to make the dyspepsia secondary to the oxaluria, others to make the oxaluria in some way dependent upon the dyspepsia. The acid theory was an outgrowth of this last endeavor. It is well known that organic acids are oxidized in the body and converted into carbonic acid and water. It is fair to presume that impeded oxidation of the organic acids that are produced by fermentation in dyspepsia may end in the formation of oxalic acid. This theory would seem to account for the majority of cases of oxaluria better than any of those that we have hitherto considered. But there is another probable source of oxalic acid in the body which has been strangely overlooked. It has been assumed, nearly without exception, that the oxalic acid that originates here is formed either in the blood or in the substance of the organs and tissues. It does not seem to have occurred to the writers upon this subject that oxalic acid can be formed, like various other organic acids, in the alimentary tract. Reading clinical observations and experiments have rendered it very probable to the writer that oxaluria may be due to this cause. Although I have consulted the literature of oxaluria quite extensively, I have only found one author who has alluded to this possibility. Chambers¹⁸ hints of such an origin in the following passage: "Chemists tell us that citric, malic, and other organic acids distributed through the vegetable world are liable to conversion into oxalic, so that it is not necessary that it should naturally be a constituent of the food eaten, but may arise during its fermentation or digestion." We are left in doubt as

to whether the author means by this that the oxalic acid may be directly produced in the alimentary canal in consequence of abnormal fermentation, or whether from the imperfect oxidation, after absorption, of other products of fermentation. He contents himself with this bare allusion to the possibility of the manufacturing of oxalic acid from the food during imperfect digestion. Medical literature, however, has recorded many facts that lend great probability to this theory. Food that does not digest ferments, or decomposes, much in the same way as it would under similar conditions of warmth and moisture outside of the body. Decomposition and putrefaction play a part in the disintegration of the food in the intestines, even in normal digestion, and this part is a much more extensive one than is commonly supposed. Every physician will be profited by reading the section in *Hermann's Handbuch der Physiologie*, in which Maly¹⁹ describes the activity of bacteria in reducing the contents of the intestines to the condition that they have in the feces. The intestines, particularly the lower portion of them, are swarming with bacteria. The feces are filled with a great variety of micro-organisms. Any one can easily convince himself of the truth of this statement by microscopical examination. Given warmth, moisture, innumerable bacteria and a quantity of easily decomposable organic matter, putrefaction is inevitable, unless some substance be present to arrest the action of the bacteria. Bile is the natural disinfectant of the intestines, but this is incapable of preventing all putrefactive changes in the alimentary tract. Indican, one of the most constant constituents of the urine, is ever a witness of the insufficiency of this anti-fermentative action of bile. Indican is derived from indol, and Maly states that there can be no indol or inflammable gas produced in the intestines without bacteria. He further affirms that the products of pancreatic decomposition do not have any physiological uses.

Digestion is essentially a process by which insoluble substances are converted into others capable of being absorbed into the blood. True digestion is accomplished in a relatively short time. Very likely, too, the digestive ferments may have some restraining influence on the action of the bacteria. But when digestion is delayed, or is not accomplished, the micro-organisms present in the stomach and intestines assert their power; and we could scarcely devise more favorable conditions for the cultivation of bacteria than exist in the lower part of the intestines. That these bacteria manufacture, in many instances, very virulent poisons, has been abundantly proven by recent researches upon the subject of ptomaines. It is a constant source of wonder to one investigating the subject that cases of poisoning of this origin are not more common than they appear to be. But, in all probability, ptomaines are not the only poisonous substances manufactured in the alimentary canal. Many organic acids are produced during the fermentation of food. Brieger²⁰ has isolated various species of bacteria existing in the feces, and has cultivated them outside the body. He also studied the action of these micro-organisms on fermentable solutions, and obtained, in this way, various organic acids. He does not record the finding of oxalic acid; but it is not evident that small amounts of the acid would have

been recognized by the methods of analysis that he employed. Investigations of this character are very important, and promise to shed a good deal of light upon questions of great physiological and pathological interest; and it is very desirable that this line of experimentation be followed out.

Flügge places oxalic acid in his list of substances resulting from the activity of bacteria. If oxalic acid can be manufactured by bacteria outside of the body, it seems altogether probable that the same process can take place in the intestines. Salkowski²¹ states that crystals of oxalate of lime are not infrequently found in microscopical examination of the contents of the large intestine. He does not say what the probable origin of these crystals is. Either they must have been taken into the body in the food, or they must have been due to the combination of oxalic acid manufactured in the alimentary canal with lime, unless we are disposed to admit that oxalic acid may be eliminated through the intestines, which seems in no way probable. We should also bear in mind that octahedral crystals of oxalate of lime, like those ordinarily found in the urine, are not common in plants containing the acid and its salts. The crystals in plants are apt to exist in irregular aggregations of these octahedral forms, or as needle-shaped crystals. We, therefore, have good reason to suppose that the oxalate crystals found in the intestines are due to oxalic acid formed in the digestive organs. Of course, if oxalic acid is formed here, there is no reason why it should not be absorbed into the blood and give rise to oxaluria. I have made microscopical examinations of the faeces of several oxaluric patients. Although I have found octahedral crystals here, I have never been convinced by chemical tests that they were composed of oxalate of lime. For several obvious reasons, it is not a very easy matter to detect minute crystals scattered through such a mass of detritus as exists here. Such examinations, however, are promising, and should be repeated.

It seems to me, in the light of what has been said, that we have a right to assert that the theory of the formation of oxalic acid in the digestive organs is a very probable one. Several experimenters have unconsciously corroborated this theory. Fürbringer²² made an elaborate series of experiments to determine the influence upon the excretion of oxalate of lime of the ingestion of alkaline bicarbonates, lime-water, and uric acid and the urates. The results of these experiments was mostly negative. In one of his observations, however, he casually records a great increase in the oxalic acid excretion coincident with diarrhoea. This occurrence is to me very suggestive. An ordinary diarrhoea means increased fermentation and putrefaction in the intestines. If oxalic acid has a source in this putrefaction, then the association of oxaluria and diarrhoea ought not to surprise us.

Hammerbacher²³ afterwards repeated some of these experiments of Fürbringer, and investigated the effect of alkalis upon the excretion of calcic oxalate in dogs. He mingled enormous doses of bicarbonate of soda with the food of these animals, and found that the amount of calcic oxalate in the urine was considerably increased. In one instance, at least, the large doses given caused vomiting and loss of appetite. The doses given ranged from five to twenty grammes.

When we compare these weights with those of the dogs experimented upon, we see that the doses were excessively great. The digestion must have been profoundly disturbed by them. If the food did not digest it putrefied, and oxaluria was the result. This may not be the correct explanation, but it appears as probable as any that we can give. It does not, however, seem to have occurred to the author.

Mills²⁴ performed some experiments upon a dog in "nitrogenous equilibrium," to determine the effects of various forms of diet upon the excretion of oxalic acid. He notes that a very large amount of the acid was excreted upon a dog following *diarrhoea*. The fact speaks for itself.

I may add that oxalic acid is frequently found in the urine of hogs. Calculi consisting of almost pure calcic oxalate are sometimes found in the bladder of these animals. I have examined hogs' urine only once; but in this instance I found a great number of calcic oxalate crystals, after allowing the urine to stand for a long time. When we consider the character of the diet, and the habits and environment of these animals, we have every reason to suppose that bacteria have an especially attractive field of operation in their intestines.

Williams²⁵ says that oxaluria in horses is apt to be accompanied by symptoms of acid-dyspepsia. The horses in which I have most often found oxaluria are those that are highly fed and little exercised: such animals are, of course, specially liable to digestive troubles.

Brunton²⁶ remarks that the deposition of oxalate of lime is usually connected with disturbances of the digestive system; and he further states that he has observed, in a hospital ward, that a deposit of this substance is commonly found in the urine after the patients have had cabbage for dinner. This occurrence serves to strengthen the theory of the formation of oxalic acid from the decomposition of food. Probably nothing would be more likely to afford an intestinal bacterium a greater opportunity for the exercise of its functions than an abundant supply of cabbage.

The association of icterus and oxaluria has been noted by certain writers. Murchison²⁷ thought that oxaluria might be connected in some way with liver trouble. As bile is the natural disinfectant of the intestines, when its flow is obstructed decomposition can more readily take place. This would be a natural explanation of the occurrence of oxaluria with icterus. Indigestion means an increased opportunity for bacteria—an opportunity that they are always ready to seize.

The writer does not claim that the theory advanced here to account for the formation of, at least, some of the oxalic acid excreted from the body has been demonstrated beyond controversy, but it certainly demands consideration. If it be true, then the treatment of oxaluria resolves itself into that of dyspepsia.

—The Grocers' Company's prize of \$5,000 for the discovery of a method for the cultivation of vaccine contagium outside of the animal body, was not awarded, and the same problem is again proposed, papers to be submitted by December 31, 1890.

CASES OF DIABETIC COMA, WITH REMARKS.¹

BY FRANCIS MINOT, M.D.

THE term diabetic coma is applied to that alarming state of insensibility, often occurring suddenly, which is sometimes observed in diabetic patients, even when the symptoms have not given rise to apprehensions of approaching death. Although the appearance of the patient is strongly suggestive of the presence of some poison in the blood, the toxic agent which causes this condition has not as yet been determined, and I am not aware of any material addition to our knowledge since the interesting paper on the relations of diabetic coma to acetonæmia and fat embolism by Dr. Fitz was read before the Society for Medical Observation eight years ago.

It is not my purpose, however, to discuss the pathological aspect of diabetic coma, but to call attention to the fact that it may occur suddenly in a patient not known to have been diabetic, or not even suspected to be ill at all, thus giving rise to much perplexity as to the diagnosis. Two such cases have come under my observation during the past year, which seem to be of sufficient importance to be reported. Each of them caused much alarm to the friends of the patient, and both were inexplicable to the physicians who were called in the emergency to see them for the first time. Diabetes is not a common disease, and coma occurring in patients not known to be diabetic is so rare, that one may be excused for not recognizing it at once.

The first case was that of a young woman, twenty years old, married, being, as was supposed, in her usual health, who was taken with vomiting in the afternoon of January 30, 1887, after eating a hearty dinner, and gradually became unconscious, remaining so until she died, at two o'clock in the morning of February 1st. I was asked to see her in consultation, a few hours before her death, by a physician who had been called in at 3 o'clock, A. M., of the 31st, having had no previous acquaintance with her. I recognized her as a patient who had been sent to me about six months previously for an opinion, by Dr. W. B. Bancroft, with a letter stating that she had the usual symptoms of diabetes, and was passing about seven pints of urine in twenty-four hours, containing a large amount of sugar. It seems that soon afterwards she became discouraged, on account of the persistence of her symptoms, and consulted various irregular practitioners, but had no regular attendant at the time of her seizure. The patient was of a nervous temperament. Her grandfather by the mother's side died, after some years' illness, of a "spinal disease and diabetes"; her father's family was consumptive, and he died of "tubercle of the spinal cord."

When I first saw her in July, 1886, she stated that the amount of urine and the general symptoms varied a good deal. At times, the quantity of urine would be normal, and once it remained so for two weeks. The appetite had been "ravenous" from the beginning. She perspired freely. When I saw her for the second time, she was four and a half or five months advanced in pregnancy. Her friends said she had felt the motion of the child for the first time the day before her attack. She was so much scented with artificial perfume, that I was unable to tell whether her breath was sweetish or not. She had a pulse of 160, the

respirations varied from 32 to 36 in the minute, the mouth was dry, the fetal heart could not be heard. She was wholly unconscious. I afterwards learned that a short time after my visit she suddenly sprang up in bed; the head was drawn downwards and to the left, pupils dilated, flexor muscles of arms and hands tonically contracted for about five minutes, after which relaxation ensued. Five hours later another attack occurred, in which she died. The urine was last voided twenty-four hours before death, in small quantity, but had not been saved. If the previous history of this patient had not been accidentally discovered, the cause of death might not have been recognized. It would probably have been reported as apoplexy or unknown.

The other case was even more remarkable, inasmuch as the patient was not supposed to be ill at all before his attack. He was a lad fifteen years old, who complained of not feeling well, but without definite symptoms, on the morning of April 17, 1887; he ate a good dinner, however, including some plum-pudding. Towards evening he felt worse, and he went to bed early. He speedily became somnolent, and, before morning, was quite insensible. A physician was called in, who was unable to account for the symptoms. I saw the boy in consultation in the forenoon, and found him in an unconscious condition; pulse 144, weak; respirations 20. There was no paralysis. The face was flushed, the cheeks cyanotic, eyes closed, pupils natural, sensitive to light. The breath had a sweetish odor. Plantar reflex good on both sides. The abdomen was excavated, showing, as did the thorax, great emaciation. In answer to my questions, his mother said that he was an active and intelligent boy, and had been in good health, so far as noticed, up to the present time, though he had been losing flesh of late. He had just had a week's school-vacation, during which he amused himself with active sports, as usual, playing base-ball most of the time. Some two or three months previously to his sickness he had wet his bed in his sleep, a thing he never did before. The amount of urine was very large, and it was noticed that after the sheets were dried they were stiff and sticky. It was then found that he had been making more water than usual; also, that he drank a large amount of water, sometimes a pitcherful at a time, and that his appetite was very great. Indeed, it seemed ravenous, and he bolted his food without chewing, in a way which had not been customary with him. His diet had been a miscellaneous one, including a good deal of fruit. With this history, there could be no doubt as to the existence of diabetes, probably saccharine, and an examination of some of the urine which happened to be saved showed that it was pale, acid, specific gravity 1028, containing a trace of albumen, hyaline casts, and eighteen grains of sugar to the ounce. The addition of tincture of chloride of iron gave a wine-red color to the urine. The patient died at midnight following, without having recovered consciousness.

These cases are examples of death occurring under circumstances of great obscurity, in which the course had been overlooked from omission to obtain the complete history of the preceding symptoms, which would have explained the cause of the patient's condition, even if no urine could have been obtained for examination.

Fatal coma is also liable to supervene unexpectedly

¹Read before the Boston Society for Medical Improvement, December 12, 1887.

in cases of diabetes which are apparently improving under treatment. The daily excretion of urine may fall to the normal amount, its specific gravity may diminish, the sugar may almost disappear, and a general amendment may take place, when the patient suddenly becomes unconscious, sometimes without obvious cause, and remains so till his death, which usually occurs within twenty-four hours, or a little later. Many years ago, I had an opportunity of observing such a case. The patient was a lady, fifty-five years old, a widow, of nervous temperament. Two years before I saw her she became insane, the effect of a severe bereavement, and was in an asylum for several months, after which her health became good until shortly before the time when she consulted me, in December, 1857. She had noticed that she was troubled with frequent micturition since the month of May previous; also, she complained of pain in the back, and afterwards, of extreme thirst. There was great debility and some loss of flesh, she having previously been quite stout. The daily amount of urine was about seven pints, its gravity was about 1040, and it contained 9.2 per cent. of sugar. She was treated with alkalis (four and a half drachms of bicarbonate of soda daily), a hot air-bath at night, and an appropriate diet. There was an immediate improvement in all respects. The amount of urine became normal, although its specific gravity did not diminish, the patient was no longer obliged to rise during the night, the thirst ceased, the skin became moist. She slept well, and was in good spirits; the strength improved, and she walked or drove out daily. On the 29th of January, 1858, more than six weeks from the time I first saw her, the weather being very cold and damp, she unfortunately went on a shopping expedition, and got chilled. There was no change in her condition on the next day, the 30th, when it was recorded: "urine varies between three and five pints" daily; "thirst very moderate, strength rather improving, some perspiration, walks out almost daily, sleeps well, is much more calm and cheerful." But on the 31st she complained of return of the back-ache and of the thirst, though there was no increase in the amount of urine. She took her vapor-bath at bed-time, as usual, but had a very restless night. At four o'clock of the morning of February 1st, and at intervals during the day, she vomited large quantities of a dark-colored, sour-smelling fluid. During the following night she became unconscious, and remained so to the time of her death, at 1 A. M. of February 3d.

At the post-mortem examination, the body was observed to be very fat. No evidence of disease was found in any organ. The kidneys appeared perfectly healthy, but a microscopic examination by the late Dr. Calvin Ellis showed that the tubuli, both of the cones and of the cortical substance, were everywhere filled with minute fat globules. Many free globules of fat were also seen, and a large amount of brownish, granular matter. These appearances in the kidneys were undoubtedly secondary.

The intrinsic cause of diabetic coma is, as I have said, at present unknown, and it must remain so until the noxious product of the abnormal processes of metamorphosis is discovered. Nor are its exciting causes much understood. In many cases, no special change in the patient's diet, no exposure to cold, or other external depressing agency, have occurred before the supervention of the comatose state. In

others, the coma has followed so closely upon fatigue, cold, excess in diet, mental emotion, etc., that it is reasonable to suppose that such influences precipitated it, at least.

The prognosis in respect to the state of unconsciousness is extremely unfavorable. Nevertheless, in a few cases there has been temporary improvement, and even complete recovery from the threatening symptoms; but this has not appeared to result from any special mode of treatment.

REPORT ON MENTAL DISEASE.

BY HENRY R. STEEDMAN, M.D.

OVERWORK IN SCHOOLS.

LUYS¹ in a recent discussion before the Académie de Médecine, takes a different view of the question of overwork in schools from that usually presented. Peter had maintained that the outbreak of pulmonary tuberculosis in the young, was intimately connected with mental over-exertion. This, Luys doubts. The two phenomena he believes have no connection; and he supports his argument by citing one thousand and eighty-six observations of patients, with what might be called chronic cerebral overwork, from paralysis agitans, mania and delusional insanity, in but six of whom was the outbreak of phthisis at all coincident with the signs of increased cerebral activity. Phthisis when it occurs, he believes to be due to unfavorable hygienic surroundings, rather than to any undue strain upon the brain.

Turning from the question of the development of tuberculosis to the main question of overwork in schools, Luys begins by giving some figures as to the anatomical development of the brain. According to Loomer, the average weight of the brain of a child of six is 1,087 grammes, of an adult 1,323 grammes, a difference of 236 grammes. Individual cases are also cited to show that not infrequently the adolescent brain before the age of twenty has reached nearly, if not quite, its full weight; cranial measurements, moreover, show that the skull is very little smaller in the youth than in the adult, one or two centimetres less in its antero-posterior diameter in children of six to ten, than in their father at forty. The difference in the fissures and convolutions of the adolescent and adult brain, is not perceptible. Therefore, being nearly, if not quite as fully developed, the brain ought to be nearly if not quite as capable of work.

Luys therefore doubts whether in the average child there be such a thing as cerebral overwork, as we see it in the adult. The child is only a small portion of the day at his studies, and furthermore, he has long vacations. Their work is much less serious and is limited mainly to the purely intellectual regions of the brain. The emotional regions and their conscious personality are entirely at rest, while in the adult every intellectual act is intensified by a still greater emotional activity which may thus more readily lead to over-exertion. The child's work, on the contrary, calls into chief activity the memory and the imagination, judgment, discernment, the conscious personality are all inactive. The disproportion between the work required and the capacity of the adolescent brain is therefore much less than has been imagined, and the

¹ L'Encéphale, Septembre, 1887.

dangers of overwork in schools have consequently been greatly exaggerated. There is, however, a class which is likely to succumb to the routine of school duties, and this class is made up of "héréditaires" who have a paralytic father or a neuropathic mother. They are fond of work, zealous and ambitious, but they soon break down, they become restless, easily fatigued, are subject to headache or insomnia or become somnambulists. They also show other symptoms of graver import; the memory fails, they become absent-minded, they suffer from vertigo, or even, as in one case, from epilepsy, as a result of overwork. They keep up with their fellows for a time, but eventually they have to give way. Physically, their heads are too large or too small for their bodies, the cranial vault is irregular in shape and the sutures are marked by irregular thickenings.

Luis, therefore, concludes that phthisis is excessively rare in a certain class of mental subjects; that the course of study should not be diminished in regard to the required amount of work, since the adolescent brain at eighteen is nearly as large as the adult brain, although it might be well to vary the mode of presentation of the subjects, so as to render them more interesting, and to appeal more to the conscious personality of the child. He believes that we must look to the future interest of the race and that the human brain is increasing in volume. We therefore should not seek to abridge a course of study, but to make it more ample to correspond with the advance in our knowledge.

THE COMMUNICABILITY OF INSANITY.

D. Hack Tuke in remarks upon *folie à deux*,² said that he believed that the influence of the insane upon the sane was exceptional, that those who became insane from association with the insane, are usually neurotic subjects or somewhat feeble-minded; that women become so affected more frequently than men; that delusions possessing some appreciable groundwork or plausibility are the most commonly transmitted; delusions of persecution and the like are often seen in these cases. Among the practical conclusions of the paper were:—(1) Medical men ought to be alive to the considerable danger of one insane member of the family endangering the mental health of another member. (2) One sister should not nurse another when the latter becomes insane. (3) Susceptible young women whether related or not, should not associate intimately with lunatics. (4) When mental disorder is transmitted or when, from whatever cause, persons who are associated become deranged, prompt separation should be effected and complete change of scene secured. The well-known rarity of insanity among attendants on insane, is illustrated by a remark of Dr. O'Meara. Only two females among the attendants in his asylum became insane during his experience of thirty-one years.

HYSTERICAL MUTISM AND MENTAL DISEASE.

Cases of hysterical mutism have frequently been reported, and although very incompletely described, the condition has been given more or less notice in most works upon hysteria. It has remained for Charcot³ to isolate the distinguishing features of this group of symptoms in clinical lectures upon this special sub-

ject. He has invested it with additional interest by revealing entirely new characteristics, throwing much light on known ones, and systematizing our knowledge of this condition, one which in all probability has its seat in the cortex, is in every case of the dynamic order, and has strongly marked characteristics which are easily recognized. Cartaz,⁴ also, in a very interesting monograph, giving the substance of these lectures analyzes the reports of twenty cases, six of which are taken from Charcot.

Bouchaud⁵ takes up the relations of mental disease and hysterical mutism. He prefaces the following account of a most unusual case by remarks upon the diagnosis. It is now, he thinks, easy to diagnose between hysterical mutism and the mutism of motor aphasia of organic origin as well as that of bulbar lesions, not to speak of feigned dumbness. As an unimpaired mental state is one of the chief characteristics of this form of mutism, it would seem impossible to confound it with the mutism of mental alienation, and this accounts for Charcot's unfortunate omission of any mention of the mutism of insanity where it is common enough, being found in delusional insanity and in melancholias, and as a frequent symptom of stupor. Sometimes it is purely voluntary, in which case it is not always possible for the observer to ascertain the nature of the delusion which impels the patient to keep silent. This explains the difficulty which may arise in deciding in certain cases whether we have to deal with insanity or hysteria.

The case in question is that of a shoemaker, twenty-six years of age. He was admitted in March, 1886, to the asylum of Lommelet, by transfer from another asylum where he had been treated since 1885. His certificate stated that he had been suffering from an attack of melancholia with hallucinations of sight and hearing. That he had developed almost complete mutism so that the precise nature of his hallucinations could not be ascertained, but to judge from his facial expression, they were depressive. His condition was thought to be stationary, and the disease probably chronic.

Soon after admission, the patient wrote a note to Dr. Bouchaud, in which he complained of vague pains which he ascribed to drugs that had been given him at the asylum he had just left.

The note gave the impression that it was written under the influence of delusions, but careful examination revealed the fact that the pains he felt were genuine, but ignorantly attributed by the patient to medicine given to procure rest and sleep when he was highly excited. The patient was found to be completely mute, but able to write, and, although ignorant, to give a sufficiently clear history. His mother died of apoplexy. One of his brothers is addicted to drink. A paternal cousin is a chronic dement in this asylum. The patient had been given to alcoholic excess since the age of twelve. At seventeen he had two nervous attacks of short duration, following altercations. They were characterized by rage, followed by general tremor and complete stiffness of the body, but no falling or loss of consciousness. He spent his weekly profits from his trade in spree, remaining intoxicated from eight to fifteen hours. He habitually drank brandy or absinthe in the morning. In May, 1885, after a debauch, having spent the night in the gutter, he lost his

²Proceedings of the Section on Psychology of B. M. Assoc. Vide Brit. Med. Journal, September 3, 1887.

³Leçons sur les Maladies du Système nerveux, Tome III, 2me.

⁴Ibid. Appendice V, also Progrès Medical, 1886.

⁵Annales Med. Psychol., Septembre, 1887.

reason and was taken to a hospital. He then had several of the above-mentioned attacks, but did not lose consciousness completely. He was tormented by countless hallucinations of sight. He believed that he had killed two people and saw their blood, and the judges who were condemning him. He saw also animals and wild beasts. This condition lasted several months. He once left his bed at night and ran naked into the yard in great fear lest he would be drowned in the sea, which he thought was rising around the building.

At this time he noticed that it was difficult for him to speak. He could not complete certain words when he began to utter them. He thus lost his speech gradually, and finally could not speak at all. In this state he was sent to an asylum, still having hallucinations of all sorts. Two months later he began to feel more comfortable, and his hallucinations began gradually to disappear. He grew calmer, and soon all his false ideas vanished. His dumbness alone remained unchanged. The physician of that asylum stated that in the belief that the patient's dumbness was feigned he placed him under special night observation for a long time in order to ascertain if he could be surprised into uttering any words when sleeping lightly, but without success. He then went to Lommelet. The record states that since his admission his condition has been the same. He was immediately given work making shoes, and showed himself to be clever and industrious. Occasionally he refused to work because his discharge was denied him, but soon becoming tired of doing nothing he returned to his bench. He has been entirely rational, manifesting no hallucination or other mental trouble whatever. His complete, absolute mutism strikes one immediately. He cannot utter a sound, making no effort whatever, and refusing to try when directed to do so. He not only does not speak aloud, but also does not even whisper. That there is no paralysis of the organs of speech is shown by the free movement of lips, tongue, velum palati, etc. He can blow but cannot whistle as he once did, for although he puts his lips in the right position he makes only a slight sound when blowing vigorously. He understands perfectly what is said to him, and reads writing readily, keeping himself supplied with paper, on which he quickly writes what he has to say. He has not had an attack of any sort since his admission, and his sense of vision, of taste, and of smell, seem to be unimpaired, except for a trifling myopia of long standing. The general sensibility is somewhat modified, and although there are no "hysterogenous points," he cannot feel a light touch on either side when his eyes are closed. Sensibility to pain is in great measure extinct, the prick of a pin causing no especial discomfort, especially in the limbs or either side. It is a question whether alcoholism or the hysterical state would account for this anesthesia. The base of the patient's tongue, or the velum palati, can be touched with a pencil or the finger without provoking reflex movements, but on pushing further nausea follows. No contractions are apparent on the application of the electric band around the arm. He never had dreams often, and none whatever since he became ill. He has occasional short darting pains in the lower part of the body and lower limbs. The knee-jerk is normal. In the way of treatment hypnotizing has been tried with a view to employing suggestion, but without success. Electricity and douches have

been equally unsuccessful. That the patient's dumbness was not voluntary is shown chiefly by his desire to return home. He was very impatient at his detention, but knew that if he recovered his speech he would be immediately discharged.

Bouchard considers this a case of hysterical mutism, complicating insanity. The analogy between the symptoms described and those given by Charcot as characteristic of hysterical mutism is complete. They are, in a few words: Sudden onset; impossibility of crying and speaking; sound mental condition; return of speech after a time, with stammering of a peculiar kind; duration variable, usually short, but extending, in some instances, months, and even years. The patient was finally discharged, his long detention at the asylum having been chiefly due to the hope of bringing about the cure of a trouble which usually disappears suddenly and spontaneously, but nevertheless may yield to such measures as were tried.

MENTAL DISEASE AND INTERMITTENT FEVER.

Lemoine and Chaumier⁶ have recently made an elaborate study of this subject, illustrated by a number of instructive cases. The following conclusions are reached:

(1) Violent mania, without clearly defined characteristics, may accompany an attack of intermittent fever in predisposed subjects.

(2) In the same class, but far less often, convalescence may be the starting-point of a mild form of insanity, stupor or mania of uncertain duration and usually curable.

(3) Old subjects of malaria, with masked manifestations, are liable to recurrent intellectual disturbance, or to chronic insanity. The diagnosis of the latter is impossible without a full previous history of the patient.

(4) There probably exists a form of pseudo-general paralysis of a malarial origin.

(5) It is an important matter in treatment to ascertain the presence or not of intermittent fever as an etiological factor in the history of all cases of insanity. Quinine gives good results in intermittent mania and its convalescence. It is apparently of no value in the chronic cases, but even in these the drug may quiet transient attacks of agitation as if they were masked phenomena of the disease.

THE PRODROMAL STAGE OF GENERAL PARALYSIS.

Dr. Savage stated at the last meeting of the International Medical Congress, apropos of general paralysis, that if any cure is to take place it is to be when the case is taken early. The longer we have experience with the disease, and the more we get the early history, the length of time which the prodromal symptoms have existed is extended. I have, within the last five or six years, made it a rule when a patient became certainly and undoubtedly general paralytic, and was recognized as such by his friends, then to issue a form of questions as to very earliest changes in character, in handwriting, in vision of one kind or another, and in a very large number of cases, eight, nine, ten, or even twelve years before the patient became fit for certificates there were signs of the disease, but I think that not in one case out of ten thousand would we be able to persuade the patient that he required rest or treatment. Especially in some cases

⁶ *Annales Médico Psychologiques*, Mars, 1887.

of syphilis, I think early treatment will do good; but I am afraid the time is very far distant when we shall be able to persuade those who break down with general paralysis that they required treatment years before.

Parant⁷ has found in certain cases a condition of intellectual hyperactivity without delirium or dementia, in the prodromal period of general paralysis. In the last few years he has had three patients, typical general paralytics, when they came under his observation whose disorder had been ushered in by the following conditions: Each of them for a period of greater or less duration before the outbreak of mental disturbances passed through a condition of increased intellectual activity, an exaltation of the mental faculties, endowing them with aptitudes utterly unknown in them before, but which no one for a moment considered a sign of disease. This arose from the fact that this hyperactivity had the manifestations and all the appearance of an entirely normal state. It seemed perfectly in keeping and reasonable. Those who manifested it did not act absurdly or inconsistently. They were not extravagant, nor did they compromise their own interests. On the contrary they conducted themselves like skilful, judicious, prudent men, and used proper means for accomplishing their purposes. A synopsis of the first case is as follows: Marked intellectual activity for two months and a half. Transformation of character and mental faculties. Unusual facility in public speaking. Period of excitement, irregular and disturbed conduct. Ambitious delusions, general paralysis, enfeeblement. Death by marasmus.

Second case. Unwonted energy in business, great courage in combined enterprises, and most successful outcome. Acquisition of a large fortune in two years. Alteration of character, exaltation, ambitious delusions, general paralysis, short period of remission, return of excitement, congestive epileptiform attacks. Death.

Third case. Unexpected development of a taste for the management of public and private affairs. Great activity. Conducts to successful issue a number of useful projects. Sudden change at the end of a year. Alteration of character, disorderly conduct. General paralysis.

Two additional cases of a somewhat similar nature are summarized as follows: First case. Sudden manifestation of great skill in military manoeuvres, excitement, general paralysis, rapid gangrene of the perineum, death. Second case. Development of a brilliant memory, dementia, maniacal excitement, general paralysis.

GALVANISM IN THE TREATMENT OF INSANITY.

Wiglesworth⁸ gives an account of some recent work of his own in this line, and comes to the generally accepted conclusion as to the value of galvanism in insanity. He also gives, however, certain details as to the best method of applying the current to the head, as well as precautions that should be taken, which have, we believe, not been laid down elsewhere. Moreover, this treatment requires to have attention called to it from time to time that the use of this therapeutic agent may not be neglected in the small class of cases in which it is really of decided service, and therefore essential.

He comes to the conclusion that, whilst the use of galvanism to the head is a proceeding which is certainly *not* going to revolutionize the treatment of insanity, this agent is nevertheless one that is capable of doing much good in certain selected cases, and that by its judicious employment we may every now and then cure cases which would otherwise drift into hopeless chronicity. The class of cases which offers the best field for the employment of this agent is that which includes examples of mental stupor and torpor, cases which are grouped under the specific designations of *melancholia attonita* and so-called *acute dementia*.

In the discussion following this paper, Dr. Urquhart inquired as to necessity for large plates, inasmuch as the current spreads in going from one pole to the other, and also if the resistance was calculated. He detailed a case of hypochondriacal melancholia, which was verging on chronicity, and recovered under application of galvanism.

Dr. Hack Tuke mentioned a case of stupor in a young lady, in which he had persistently used the constant current, but without effect. He had always thought there was strong *a priori* reasoning for expecting good results from galvanism in cases of mental stupor. He referred to the modified good effects obtained from the electric bath. Professor Ball had recorded in *L'Encephale* some striking cases of cerebral torpor which he had treated by galvanism with very satisfactory results. He (H. T.), thought Dr. Wiglesworth had given reasons for encouragement, although not to as great an extent as he had hoped.

Reports of Societies.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.

E. M. BUCKINGHAM, M.D., SECRETARY.

DECEMBER 12, 1887, the President, DR. O. F. WADSWORTH, in the chair.

DR. FRANCIS MINOT read a paper entitled

CASES OF DIABETIC COMA, WITH REMARKS.¹

In connection with Dr. Minot's cases of diabetic coma,

DR. T. M. ROTCH reported an interesting case of diabetes with the fatal result precipitated by erysipelas and ending in coma.

A lady, forty-one years of age, came under his care March 24, 1887, to be treated for an efflorescence of the skin, pronounced by Dr. Wiglesworth to be a rare form of molluscum. The patient had had three children, the oldest fourteen years previous, the continuation being accompanied by puerperal eclampsia, and followed by erysipelas of the legs. Some years later there was a miscarriage. Five years later a girl was born, and one year later a boy. The husband and children are living and in good health. For some years the patient had had pain and numbness in hands and feet. The molluscum first appeared five years ago, then disappeared entirely, returning one year ago, disappearing, and again returning four months ago. The skin was very sensitive, the slightest touch or tap causing exquisite pain, but there being no especial pain on deep pressure. The appetite was good. The bowels were regular. For the past year

¹ See page 69 of the Journal.

⁷ Annales Medico Psychologiques, Sept. et Juillet, 1887.

⁸ Journal of Mental Science, Oct., 1887.

she had been losing somewhat in weight, and at times had been very thirsty. Nothing especial noticed about urine, but this, on examination, was found to be increased in amount, and to have a specific gravity of 1032. Patient felt weak and very restless.

April 13th the patient was put upon diabetic diet. In a few days the restless feeling passed off, and there was a decided improvement in strength and in her general condition. An examination of the urine by Dr. Wm. B. Hills gave the following result:

Color, pale; reaction, acid; urephain, normal; indican, normal; urea, diminished; albumen, trace; sugar, four and a half per cent.; bile pigments, absent; amount in twenty-four hours, seventy ounces; specific gravity, 1032; amount of sediment, considerable; chlorides, slightly diminished; alkaline phosphates, slightly diminished.

The sediment consisted of a considerable amount of pus, which probably was caused by leucorrhoea, as there was no other evidence of an inflammatory condition. There was also evidence of a hyperæmic condition of the kidney, probably excited by the sugar in the urine.

April 20th the patient complained of sore throat. Temperature, 100.4°, pulse 120, with the fauces much reddened. This continued on the 21st with a slight appearance of the catamenia and epistaxis and a very restless night.

April 22d. Temperature, 103°, pulse 120. Erysipelas of the nose and face.

April 23d. Erysipelas has extended to forehead; and on the 24th to left ear and scalp, and then to right ear. Strong odor to urine. Temperature 103°, pulse, 120. Tongue moist, and not especially coated. Mind clear.

April 25th. Erysipelas fading in the morning, but in the afternoon appeared on left side of face again, and extended to back of neck.

April 26th. Erysipelas had extended half-way down the back, but the mind was clear and the appetite fair.

April 27th. Erysipelas has almost reached the waist, and has covered the whole face, ears and scalp. The epistaxis and vaginal hemorrhage have continued in slight amount. Pulse, 114, temperature 100.8°.

April 28th. Breathing somewhat labored and mind somewhat dull, but easily roused, and nothing abnormal detected in lung. Strong saccharine odor to breath. Mind became more dull during the day, and this very much increased during the night, the patient being in a state of sopor, but it being possible to rouse her up to within four or five hours of her death, which occurred quietly early on the morning of the 29th. There was no notable decrease in the amount of urine, which remained at seventy ounces.

DR. R. H. FITZ remarked that the chief interest in cases of diabetic coma still relates to the causation. In the past few years the investigations of v. Jaksch have been especially noteworthy. It has become recognized that the coloration of diabetic urine by ferric-chloride is due to diacetic acid and not to diacetic ether. When this former substance is present in the urine the term *diaceturia* is applied.

Diacetic acid, when introduced into the blood, seems comparatively harmless, and the nervous symptoms in diabetes, formerly attributed to acetone, cannot be due to diacetic acid. It is generally admitted that acetone is frequently present in the breath, blood

and urine in diabetes, while diacetic acid is most constantly present only in the severer cases. As both acetone and diacetic acid appear to result from the deficient oxidation of the products of albuminous metamorphosis, it has been suggested that a *diaceturia* may indicate an extreme degree of incomplete oxidation. Its presence, therefore, in the urine would show an extreme quantity of acetone in the organism. Reported experiments on the poisonous effects of acetone are somewhat contradictory, but the possibility of this agent, in sufficient doses, producing severe nervous disturbances must be admitted.

The positive value of the ferric-chloride test in determining the gravity of a case of diabetes is confirmed by the most recent observations. A small quantity of a moderately concentrated solution of the chloride of iron is added to the urine which becomes of a dark red (claret) color if diacetic acid is present. The color fades rapidly when the urine is boiled. If the urine is first boiled and the ferric-chloride then added there is little or no discoloration.

Since an exclusively albuminous diet will cause the presence in the urine both of acetone and of diacetic acid, it is important to bear this possibility in mind when applying the ferric-chloride test. A mixed diet, however, will cause the rapid disappearance of the diacetic acid, except in the graver cases of diabetes. The speaker is indebted to the recent communication of Prof. Rossbach, of Jena, on *acetonuria* and *diaceturia* (August Med. Central Zeitung, 1887, xciii, xciv.)

DR. F. C. SHATTUCK called attention to the researches of Stadelmann and others with reference to the toxic agents causative of diabetic coma, and the means of destroying their activity. It has long been a matter of observation that the reaction of the urine in diabetes is strongly acid, and Stadelmann has shown that this acidity is due chiefly to the presence of oxybutyric acid, which is excreted in combination with an alkaline base, especially ammonia. Experiments with the introduction of acetone and aceto-acetic acid into the system render it improbable that they are causative of diabetic coma. They have toxic effects, but these are mild in degree, and quite different in character from the striking symptoms characteristic of diabetic coma. These symptoms do, however, resemble those which can be produced in animals, in the *graminivora* far more easily than in the *carnivora*, by acid saturation of the system. The application of this theory is an obvious one. Diabetic coma is to be prevented by the administration of alkalis in sufficient doses to materially reduce the hyperacidity of the urine, and treated, when already present, by the intravenous injection of an alkaline solution. The latter has been practised several times, unsuccessfully it is true, but enough alkali was given in no case to make the urine alkaline, and some transitory amelioration of the symptoms was noticed. Lépine injected forty-four grammes of bicarbonate of sodium.

Stadelmann states that the introduction of the alkaline solution into the rectum or stomach — when coma is present — is not to be relied upon, and, when put under the skin, it causes abscess. In view of the seeming accuracy of the observations which have led to the formulation of this theory, their confirmation by others, the inadequacy of other theories, and the uniformly unfavorable termination of diabetic coma, as well as our powerlessness to prevent its occurrence, this method certainly deserves careful attention.

The speaker added that he had recently been struck by the excessively acid reaction of the saliva in a diabetic case.

Dr. J. J. MINOT remarked that the intravenous injection of carbonate of sodium had been successful in a case of diabetic coma reported by Minkowski.

Dr. F. W. GOSS, with reference to Dr. Rotch's case, mentioned one in which thirty or forty grains of sugar were excreted to the ounce of urine. This case terminated with facial erysipelas, coma, and death, the urine being for the last day or two almost free from sugar.

Dr. H. W. WILLIAMS thought there was an interesting analogy between these cases of coma occurring in diabetes: where there had been but slight apparent disturbance of the health, and the similar instances observed in Bright's disease; where coma not infrequently supervenes, without warning, in persons who had not appeared to be subjects of any grave affection of the system, but in whom ophthalmoscopic investigation of the eyes, made to ascertain the cause of diminishing vision, had disclosed the existence of extensive albuminuric degeneration of the retina, which evidence was corroborated by examination of the urine. The patients declare themselves free from any symptoms of renal disease—in some instances, even until the fatal attack of coma.

Dr. F. B. STEPHENSON, of the Navy, asked the Society if there was any observed relation between this disease (diabetes, which seemed, often, to arise without evident cause) and temperaments of different individuals. For instance, does it occur more frequently in those of nervous, lymphatic, or nervo-lymphatic temperament, than where the constitution is of other type?

Dr. ROTCH answered that the patient whose case he had reported might be said to be nervous.

Dr. H. F. VICKERY reported that the ferric-chloride test had been used in vain in a diabetic patient of Dr. Whittier's at the Massachusetts General Hospital, although the disease was advanced and the patient drowsy, with a mind that was not clear.

Dr. KNAPP said that there might be some confusion in the chloride-of-iron test of the urine. If the patient has been taking salicylic acid or salol, which Ewald, in testing the muscular activity of the stomach, finds is converted into salicylic acid by the alkaline intestinal juice, the urine will take on a dark-reddish or purple-brown color on adding tincture of the chloride of iron. In two cases of diabetic coma that he had seen, the symptoms of diabetes had not been of very long duration—in one case six weeks, in the other less than a year. Some three or four years ago, several cases were reported in the *Lancet*, in which the preceding symptoms of diabetes had likewise not existed for a long time. He did not know whether cases had been reported where coma came on in patients who had had the symptoms of diabetes for six or eight years, or not; but he would like further information on the point.

Dr. F. C. SHATTUCK remarked, with reference to this point of coma in recent and old cases, that coma may supervene in any case of true diabetes; though, as Ralfe, whose experience has been large, states it is more common in young persons, notoriously those in whom the disease is most grave.

Dr. D. D. GILBERT said that he was interested in hearing allusion made to a case of diabetes at the Massa-

chusetts General Hospital, where the patient's mental condition is cloudy, although he is not absolutely drowsy. He had under his care, several years ago, a gentleman afflicted with diabetes, who was subject, during the last year of his illness, to periods of intoxication, as if from alcohol. These were so marked that, although a strictly temperate man, he was accused by business associates of habits of drunkenness. About three years after the discovery that he was a diabetic, he died in a state of coma. The speaker has also at present under his care a gentleman over sixty years of age, who has been known to be diabetic for seven years, and who is now subject to similar fits of exhilaration or intoxication, accompanied by delusions, hallucinations, and general obscurity of mind. These attacks sometimes last for several days, but are more or less relieved by a purgative, although his bowels are regularly open. The reporter looks for an ending in diabetic coma.

SACCHARIN.

Dr. JOHN HOMANS, 2d, spoke of saccharin as offering an excellent substitute for sugar in the diet of diabetics. In theory, it is not absorbed, while it is extremely sweet. It may be used in tea or coffee, or spread upon bread, and it is of some little comfort to the patients. He has used it in two cases. In one, the quantity of sugar excreted was not altered. The other has not yet been observed long enough to entitle him to draw conclusions.

Dr. F. C. SHATTUCK added that saccharin is also very useful in custard, made with cream, ice cream, and the like—articles which, without sweetening, are not palatable. It is soluble in boiling water, or, as Dr. R. Sturgis states, in cold water containing a small quantity of alkali in solution.

Dr. A. C. HEFFINGER, of the Navy, showed by invitation

PLANS FOR CIRCULAR PAVILION WARDS

He states that the first modern construction for hospitals was proposed at Paris in 1788, but that it was not until 1839, that the first pavilion hospital was begun there in accordance with these plans, and this was not completed until 1853. The wards contain each twenty-four patients. In 1858 an English army surgeon, Herbert, proposed a two-story pavilion hospital. The wards are, however, long, cheerless and draughty. A pavilion hospital was constructed at Berlin, with wards for twelve patients, in 1860 to 1872. Pavilion hospitals, with modifications to suit the climate, followed at Riga and at St. Petersburg. The French, however, returned in the new *Hôtel Dieu* to the old plan of a block hospital. The Royal Edinburgh and West Glasgow Hospitals are built upon a different plan, but have gothic arched ceilings. The Johns Hopkins Hospital is the most-nearly perfect in this country. It contains two-story and one-story wards, parallelograms and octagons. The important points to be considered in ward-construction are area, cubic space, light and a supply of pure air in motion as well as convenience for service. What form most nearly meets these demands? The original long parallelogram ward is subject to draughts, it is neither cheerful nor convenient for administration. The square wards of the Massachusetts General Hospital constructed in 1842 and 1872, are an improvement upon this, but they are inferior to the octagons of the Johns Hopkins. Multiplication of angles in the octagon is, however, a

needless obstruction to ventilation, and the speaker holds that the circle with its absence of angles, capacity for receiving light from all sides, and its convenience for service from the centre, is the ideal form. By making the coiling a parabolic dome, thus doing away with all angles except where the wall and floor meet, ventilation becomes almost automatic. The City Hospital of Antwerp, constructed in 1873, contains two-story pavilions with circular wards but without a domed roof. Although both Egypt and India contain somewhat ancient, circular buildings, and although Professor Marshall proposed this form for the new University Hospital in London, yet the first practical observation of its advantages was made by a Scotch surgeon; who having the care of wounded in war in Chili, noticed that those treated in the domed churches of the country did better than those in convent rooms of parallelogram shape. This was in 1840, and he being later in Australia, proposed this form for a hospital at Melbourne, in 1854, but his plans were rejected.

In the octagon wards of the Johns Hopkins Hospital, the windows are double and both inner and outer windows can be opened either at top or bottom. Ventilation is farther secured by foul-air pipes from the circumference, passing under the floor to a central vertical shaft, which is heated. The air from each bed is therefore aspirated away by itself.

The plans designed by Dr. Heflinger provide for two circular wards connected by a central administration building and they have been approved by the Secretary of the Navy, and by the Surgeon-General. The appropriation by Congress is, however, not large enough to allow of the completion of the whole design at present.

SOLITARY TUBERCLE OF THE BRAIN.

DR. T. M. ROTCH presented for inspection the result of an autopsy made on an infant under his care. Dr. William F. Whitney had made the examination and reported: a female infant, age thirteen months, extremely emaciated; caseous tubercle of post-bronchial glands; tubercle of lungs with a slight amount of broncho-pneumonia; milary tubercle of pleura, liver and spleen; caseous tubercle of mesenteric glands; milary tubercle of pia mater at base of brain, but no especial exudation, patches of solitary tubercle as large as a ten-cent piece in lower left cerebellum and in the left temporal and occipital lobes and the right frontal lobe of the cerebrum.

Dr. Rotch also made some remarks on the differential diagnosis between infantile atrophy and tuberculosis, in a number of cases that had recently been under his care.

RHODE ISLAND MEDICAL SOCIETY.

GEO. D. HERSEY, M.D., CORRESPONDING SECRETARY.

QUARTERLY MEETING, September 15, 1887.

DR. PHILIP K. TAYLOR, of Wakefield, reported a case of ovarian cyst treated by multiple aspirations. The patient was of New England birth, unmarried, had suffered from spinal disease in childhood, and never enjoyed robust health. In 1872 she began to have some inflammatory trouble of the uterus and its appendages, and in the spring of 1887, when just past her sixty-eighth birthday, noticed increased fullness in

the left inguinal region, where an ovarian tumor rapidly developed. In the following October her physicians, deeming ovariectomy inadvisable, aspirated the tumor, withdrawing seventeen pints of dark brown fluid. From this time until her death in April, 1887, the tumor was aspirated thirteen times. The aggregate amount removed was six hundred and six pints. The largest quantity withdrawn at a single aspiration was sixty-two pints. The first few operations were attended with some abdominal inflammation and irritation of the bladder, though only once did these complications threaten serious trouble. No unpleasant symptoms followed the later aspirations. During the last two years of her life she suffered from a broken-down mammary cancer and a second intra-abdominal growth, which at the autopsy was found to be attached to the liver. She died of cerebral softening, which produced paralysis very similar to that caused by apoplexy.

QUARTERLY MEETING, December 15, 1887.

DR. W. J. McCaw reported a case of

RUPTURE OF THE SMALL INTESTINE FROM KICK OF A HORSE. — DEATH IN THIRTY-THREE HOURS.

A. M., aged twenty, was admitted into Rhode Island Hospital, service of Dr. Mitchell, December 1, 1887, at 2.30 p.m., having been kicked in the right side of the abdomen by a horse, two hours before. He was suffering great pain, extremities cold, pulse 80 and good, temperature 99° F. No external wounds or bruises. He was put to bed, and under morphine soon became quiet and fell asleep. He awoke at 7.30 p.m., and, as he could not pass water, was catheterized. Vomited after drinking milk. At 11 p.m. he complained of general abdominal pain, especially in the hypogastric region. The catheter was again introduced and three ounces of clear urine removed. Turpentine stupe over abdomen. Morphine as required. The next morning he was very restless; pulse variable and weak; temperature 102°; but little tympanites. Passed water without assistance. Vomited several times during the morning. Cold applications to abdomen. The patient slept most of the day, and at 4 p.m. sank into a stupor. Stimulants failed to arouse him, and he died at 9.30 p.m. — thirty-three hours after injury.

Autopsy thirty-six hours after death. No external marks or evidence of injury. The thoracic organs, as also the stomach, liver, spleen and pancreas were in normal positions and uninjured. The omentum and intestines were adherent and bathed in purulent fluid. Eight ounces of pus and fecal matter were found in the abdominal cavity. About three feet from the ileo-caecal valve was a transverse rent of the ileum three-quarters of an inch in length.

DR. W. B. GOLDSMITH reported a case of

STUPOR FOLLOWING INJURY TO THE HEAD.

The patient was a retired merchant, aged fifty-seven, a man of unusual business capacity and excellent mental balance. He was very actively employed, and had much responsibility and anxiety by reason of his connection with a variety of public and private enterprises. On June 22d he was thrown from a tricycle, and struck with great force on his shoulder and head, the blow upon the head coming upon the left frontal protuberance. He was momentarily insensible, but

soon rallied sufficiently to walk with assistance to his house, which was only a few rods distant. A period of nearly three months elapsed after the injury without symptoms sufficiently serious to attract much attention.

In September he began to have severe headache, chiefly in the left frontal region, but not confined to that locality. After two weeks the pain became more severe, was continuous day and night, and more strictly confined to the region of the blow. At this time physical examination disclosed little abnormal. There was no photophobia; the pupils were rather small, but not markedly so, equal and reacted to light. Muscular power, cutaneous sensation and the skin and tendon reflexes were normal. Pulse normal. He was treated by absolute quiet and rest, in a darkened room. Headache continued very severe, except when controlled by large doses of anodynes. In the third week his conversation wandered incoherently, though no active excitement was present. Gradually this changed to a condition of mental stupor. He was insensible to noise and light; gave no evidence of pain, and showed little or no recognition of those about him. There was great motor activity. He continually writhed and twisted into every possible position except the supine. The most favored one was that in which he rested on his face and knees, the knees being flexed close upon the abdomen. He was continually grasping and pulling his bedding, or whatever was within reach. He took liquid food, and slept by short snatches without much medicine. Urine and faeces passed involuntarily. After four days the restlessness decreased, and was replaced by increasing stupor and somnolence. During the succeeding week he had three attacks of extreme prostration, in which his breathing became stertorous and slow, not more than seven or eight per minute, and his pulse faint and interrupted. He gradually regained strength, became entirely rational, and has continued so for two years.

Dr. Goldsmith remarked that the exact pathological lesion existing in this case could only be guessed at. It seems not improbable that it consisted of the minute punctiform hemorrhages which various observers have found scattered through the brain after falls that resulted fatally. These may have been so small that the effusion was absorbed without permanently injuring the nervous tissue.

The President appointed the following delegates to Medical Societies:

Maine Medical Association, W. F. Hutchinson and F. B. Fuller; New Hampshire Medical Society, G. D. Hersey and G. T. Swarts; Vermont Medical Society, W. R. White and G. W. Porter; Massachusetts Medical Society, Albert Potter and W. B. Goldsmith; Connecticut Medical Society, A. G. Brown and W. H. Palmer; New York State Medical Society, F. H. Rankin, and Charles O'Leary; New York State Medical Association, J. W. C. Ely and J. W. Mitchell; Medical Society of New Jersey, Herbert Terry and J. E. Perry.

— A child being sick in New York with remittent fever, a telegraphic message was sent to "the great mind healer" of Boston, who "worked on" her for an hour, through a distance of 250 miles, and left her "as well as ever."

THE BOSTON Medical and Surgical Journal.

THURSDAY, JANUARY 19, 1888.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States and Canada; \$6.00 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 94 Boylston Street.

All letters containing business communications, or referring to the publication, subscription or advertising department of this journal, should be addressed to the "Manager of the Business Department," Medical and Surgical Journal, 94 Boylston Street.

Remittances should be made by money-order, draft, or registered letter, payable to

CUPPLES AND HURD,
94 BOYLSTON STREET, BOSTON, MASS.

ARE MODERN TOWN-POPULATIONS DEGENERATING?

NEARLY a half century ago public attention began to be directed to the devitalizing influences of crowded populations, and to the immense growth of disease and pauperism. Paris was then a nasty city, with its filth running in the street gutters. London drank its own sewage. There was no city in the world with decent water-supply or sewerage, and mines or factories were crowded with underfed, undersized laborers. Political economists, philanthropists, even the essayist and poet, were filled with dismay at the rapid degeneracy of the human race crowding into manufacturing towns and into cities; and the fact of this decay was fully proved by the investigations of an English royal commission, and a most remarkable report by Mr. Edwin Chadwick on the condition of the laboring population of England, which was the incentive and the beginning to sanitary and industrial improvement in the conditions of life among the masses.

Such vast benefits have since then arisen to the laborers of the world in purer water and air, improved dwellings, increased wages, shortened hours of work, better food, and the many advantages arising from an enlightened and philanthropic administration of public affairs, that many thoughtful students of the problem are beginning to consider whether or how far physical deterioration is a necessary result of the present tendency of the population to aggregate in the cities.

Huxley, on the one hand, points to the most wretched poor of East London, crawling under bridges, sleeping in hogsheads, half-starved, in rags and moral degradation, while others say that such people not only gravitate to the cities, but are found in the country also, the County of Donegal, Ireland, for instance, having fully as degraded a population sleeping in mud huts or caves. The question is not easy of solution, especially now while we are in the experimental stage, so to speak, of it, and are still collecting evidence.

Dr. Milner Fothergill has recently published in the *National Record*,¹ his paper, read before the British Association for the Advancement of Science, on the "Effects of Town Life upon the Human Body." He quotes Cantlie, Walsh and Ferguson, who have observed degeneracy in their towns, and Sir Thomas Crawford, who points out the large proportion of rejections of army recruits from towns for physical unfitness. He also states his own opinion that town residence is changing the Anglo-Dane into the small, dark, Celtic type, whom the Norseman dispossessed, the modification being a reversion to an earlier, lower, ethnic form. The town-dweller, according to him, has a more precocious nervous organization, and less perfect digestive organs, so that he inclines to a flesh diet to the extent of entailing a long series of morbid sequences from digestive incapacity, including Bright's disease and phthisis. He draws, also, a somewhat sensational picture, possibly suggested by Sir Crichton Brown's superficial report on the London schools, of the already taxed system of children staggering under the added burden of its lessons — true enough if not overdrawn.

Another side of the question is presented in a paper on the physical condition of the masses, in the October number of the *Fortnightly Review* by the distinguished anthropologist, Mr. Charles Roberts, who thinks that Brown's report did not fairly represent the physical condition of London school children. He dismisses Fothergill with the remark that his experience led him to believe that his patients in hospital eat too much of food that conduces to gout, dyspepsia, and Bright's disease "which form the scourge of degenerating town populations." He also shows that the statistics of recruiting for the army not only have been quite incorrectly reported by Crawford, from his not understanding all the circumstances of the case, but that, so far as they go, they indicate a physical improvement in the town-dweller between 1860-64 and 1882-86. Roberts adds, "If we may accept the army as a standard of the physique of the laboring classes, the nation is stronger and healthier now by nearly ten per cent. (9.78) than it was twenty-five years ago." He points to the lowered death-rate in London (19.9 and in Hampstead 12.2) to the improvement in the condition of the people from sanitary and social legislation, to the increase and duration of life and to Dr. Farr's evidence that the increased duration of human life in England is lived at useful ages and not in childhood or infancy. He also quotes Mr. Giffen's address on the "Progress of the Working Classes" as showing that wages have increased 33 to 100 per cent. and that the consumption of such ordinary articles of diet as bacon, butter, cheese, currants, potatoes, rice, cocoa, coffee, flour, sugar and tea, had risen from 65.25 pounds per head, of the total population in 1840, to 351.04 pounds in 1881. It is also shown that the purchasing power of wages, in food, clothing and rent, is nearly double what it was in 1839.

A most striking fact is in the decrease in pauperism from 1 in 16 in 1849 to 1 in 34 in 1886, and the increase of savings-bank deposits from 13½ millions in 1851 to 80½ millions in 1881. Mr. Roberts calls attention to the sort of industrial selection that draws the smaller and weaker of the laboring classes to cities and thinks it obvious that the difference in the physique of town and country populations is not entirely, or even largely, due to physical degeneracy, as is so often asserted by persons who have not been at the trouble to seek for the real cause. Degeneracy of the human species, even under the adverse conditions of our crowded slums in towns, being not so easy a matter as many people imagine. He finds physique a quality of the individual, and its variations dependent on and controlled by food, exercise and sanitary surroundings, so that he has little cause for anxiety, but rather good grounds for congratulation on the future of the national physique. The taste for athletic exercises, gymnastics, boating, skating and cycling, so enthusiastically practised by the educated classes, is extending to the masses; while the agitation for the introduction of physical training, technical education, and handicrafts into elementary schools promises well for the future of their children. Much, very much, remains to be done to rescue the still underfed and over-crowded town population from the insanitary conditions that environ them; but beyond what is already being done, the chief thing to do now is to impress on all persons having charge of the education and management of children, that physical activity is the law which regulates the growth and development of the body and lays the foundation of both a good physique and an active, intelligent, and teachable mind; and to secure this more time, and more skill in teaching physical exercises in schools, and more open spaces and playgrounds, are absolutely necessary.

As is usually true, *in medio tutissimus ibis*, the truth lies between the two extremes, and, in this case, much nearer the position of Mr. Roberts than Dr. Fothergill's. That city life is enervating to those who cannot get away in summer is beyond dispute. That it is far less so than twenty-five years ago, in spite of the enormous increase in the growth of cities, is equally true. There are, also, certain compensations in the greater comforts, better protection from the weather, more suitable food, etc., in the city, to say nothing of the mental diversion afforded there. The next quarter of a century will do much to solve the problem, and we shall look forward to the results of still greater sanitary and social improvements in city life in a very hopeful frame of mind for the human race.

— At a meeting of the Council of the University of the City of New York, held January 9th, it was announced that Dr. William Gilman Thompson, who has for some months past been one of the lecturers on physiology, had accepted the Chair of Physiology in the Medical Department.

¹ October, 1887.

A LAYMAN'S VIEW OF WINTER HEALTH-RESORTS.

A KNOWLEDGE of the climate and other conditions affecting comfortable living in the various localities claimed as health-resorts, is necessary for all physicians who have patients among the classes peculiarly able to avail themselves of change of place as a factor in the treatment of disease. Yet such knowledge as regards many useful localities is not always easy to gain. The physician cannot personally investigate a large number of such places, unless he habitually devotes his vacations to that object, and even such information as he may have gained by his own observation becomes, upon many points, useless after the lapse of a few years. The hotel which he found good or bad has very likely changed hands, and is conducted on a different plan. Drainage which was adequate in the day of small things, when there were but few houses in the place, may now be sadly lacking in safety; and, conversely, a place which he knew as unprovided with sewers, may have been in more recent times supplied.

For the dissemination among the profession of information as to various health-resorts, societies like the American Climatological Society perform a most useful work. Yet the medical reports on the character of various places in this regard do not always enter into that detail regarding expense, travelling facilities, opportunities for amusement, etc., which have a bearing almost as important as the climate itself on the patient's prospects for receiving benefit. On the other hand, lay opinion cannot always be relied upon for the distinctively climatic features of a place, while its publication is often inspired by a merely commercial motive.

In a recent number of the *Harpers Monthly Magazine* (November, 1887), a layman, Mr. Wm. Smith Brown, has an article on the winter climatic resorts of three continents, which is based on an exceptionally wide personal experience, covering some forty years of travel; and while it distinctly disclaims any medical knowledge, for which the physician can go to other authorities, it gives with unusual fullness the unfavorable side of each place in such a way that the physician can see what its medical bearings must be, and anybody can see what its practical inconveniences are. It is true that in some instances the author is under the necessary limitation referred to above, of not having visited the place for some years, but in such cases he is often able to give from reports of others the intermediate changes. He has the further advantage of evidently not being connected with anybody's advertising department.

Space, of course, does not permit us noticing Mr. Brown's remarks in any detail. Naturally, much relative attention is paid to the resorts, both European and American, with which the medical, as well as the general public is most familiar. Of each of these places, the unfavorable side is presented with as much fullness as the favorable: for instance, the winds and

fogs of Biarritz, the rains and the cold changes of Pau, and the general fact that all Mediterranean ports are situated on bays into which the sewage empties, without any active river currents or tides to carry it away. The author doubts if there is any likelihood of fixed disease of the lungs being cured in any of the resorts in the south of France.

As to the Nile, we are told that apart from its expensiveness (the cost for each person of living on a dahabeeyah, which is the only comfortable means of living for a serious invalid, being about ten dollars a day), there is much dust, with frequent sand-storms, which are, of course, especially irritating to weak lungs. Algiers, or rather, its suburb, Mustapha Supérieur, he regards as, on the whole, better resorts on the north side of the Mediterranean. But there are no good hotels, except in the town, which is somewhat malarious, and the villas, which it is necessary to hire in order to live comfortably, are high-priced.

Of American winter resorts, Mr. Brown speaks of Colorado, Minnesota, Northern Michigan, the Adirondacks, and Lakewood, New Jersey, as examples of the "cold and dry" climate. California has the disadvantage, to Eastern invalids, of requiring a long car-ride, going and returning, and the winters are damp, the entire rain-fall of the year occurring between October and May. With many admitted natural advantages, Santa Barbara is windy, and sometimes foggy. Los Angeles and San Diego he considers more desirable as permanent residences, or as places of resort for the tired, than as sanatory in cases of established consumption.

Asheville, N. C., and Aiken, S. C., he considers to be in the main favorable for consumptives from the middle of April to the middle of December, but for the other four months to be too cold and variable, and, in the case of Aiken, too windy for invalids to be able to lead an out-door life. Asheville, like other resorts in the South, as well as elsewhere, needs an improvement in sanitary conditions proportionate to its growth.

For such patients as require a moist, warm climate, Mr. Brown considers Nassau the most desirable resort for English-speaking people, and he says that while he has known invalids dangerously ill with the early stages of consumption to recover in other localities, Nassau is the only place where he has known people to recover who have been pronounced by eminent and reliable diagnosticians to be in the advanced and "incurable" stages of the disease. Such recoveries have occurred in persons who went to the island, year after year, in November, and remained until May.

ANNUAL REPORT OF THE NEW YORK STATE BOARD OF CHARITIES.

THE 20th annual report of the New York State Board of Charities presented to the Legislature, January 12th, gives the number of insane persons in the institutions of the State on the 1st of October last, as 14-

062, an increase in this class over the previous year of 524. Much of this increase in the number of insane is declared to be due to immigration, and the Board advocates certain amendments to the Federal law regulating immigration, with a view to the remedying of some of the evils now existing in connection therewith. The portion of the report relating to the commitment and detention of the insane is especially referred to by the Governor in his annual message. The Board recommends that the Legislature guard against unnecessary, hasty and unjust commitments to State or county asylums for the insane, and also secure protection to the inmates of such institutions against their continued detention when the necessity therefore has ceased. The opinion is expressed that the legislation desired should cover the following points:

First, directions for commitment on certificates of the physicians in the case, at the outset, shall be by court decree after examining the person in question, under provisions similar to those of the State of Massachusetts.

Second, more absolute provisions for the discharge of patients by the Commissioner of Lunacy, by procedure similar to that of the State of Pennsylvania.

Third, the enactment of a provision of the Scotch lunacy law requiring the superintendent of every asylum for the insane, to yearly make affidavit that one month prior he has reviewed the cases of all patients under his care in the institution, and that their continued detention in an asylum is necessary for their welfare or the public safety.

SMALL-POX ON THE PACIFIC COAST.

THE Supervising Surgeon-General, Marine Hospital service, reports, in his circular dated January 13th, that the number of cases of small-pox in San Francisco during the year 1887 was 166, and during the period from January 1st to 5th, 1888, there have been twenty-five cases. Of these, fourteen were among the Chinese. The disease was brought to San Francisco early in May by one of the China steamers, but did not prevail to any extent until November. On December 29th the disease was declared to be epidemic by the Board of Health. All cases, on being verified, are immediately sent to the hospital, with their bedding and clothing; the premises are fumigated, and all persons living in the neighborhood are vaccinated if possible. Vaccination offices have been opened in various parts of the city. No children are admitted to the public schools without having been previously vaccinated. Over thirty thousand vaccinations have been made at the office of the Board of Health during the past six months. Under the circumstances, the Board of Health is of the opinion that the disease will soon be stamped out.

Passed Assistant Surgeon S. C. Devan, M. H. S., reports from Port Townsend, Washington Territory, under date of January 1st, 1888, that because of the action of the Board of Health of San Francisco, Califor-

nia, in proclaiming the existence of small-pox as an epidemic in that city, the Board of Health at that port have issued instructions, under cover of date December 31st, 1887, to their health officer to subject all vessels from the port of San Francisco to rigid examination. He also reports that there are three accredited cases of this disease at Seattle, Washington Territory.

THE RULING PASSION STRONG AT THE DEATH-BED.

IN connection with the disastrous accident on the Boston & Maine Railroad last week at Haverhill, Mass., in which ten persons were killed, and many more wounded, the horrors of the situation seem to have been enhanced to an unusual degree by the unseasonable "enterprise" of the interviewing reporter. This functionary of one of the Boston dailies, after giving with professional pride his success in interviewing the wounded and dying, chronicles with cheerful impartiality the evidence of his capacity for making himself a nuisance in these words from one of his victims: "Oh, Mr. Reporter, don't ask me any more: I can't stand it," and, with an exclamation of intense pain, he sunk deeper in the snowy-white pillows, and rolled his eyes with a look that told plainer than any words how acute were his sufferings."

The reporter did set a limit to his impertinence in one other case, though with a singular tone of apology to the public and his employers for his apparent dereliction of duty: "The last victim in this room was a Swede named Nils Bonin, who was asleep when the *Herald* man approached his cot. His face bore no marks of disfigurement, and he was breathing so regularly that it seemed a pity to awaken him. The reporter did not attempt it. One of the corps of hospital attendants said Nils was deaf and very hard of hearing. This was another argument against forcing the unlucky Swede to awake and tell what he knew."

Certainly, it seems very strange that the authorities in charge of the wounded passengers should have allowed these sufferers to be disturbed in such a way. The wards of a public hospital ought, as much as a private house, to secure exemption for their inmates against the persistent and predatory interviewer.

MEDICAL NOTES.

—Dr. J. P. Wall reports that the rumors of the presence of yellow fever at Tampa are without foundation.

—A foreign contemporary reports that some little time ago in Belgium a man was accused of the rape of a little girl. On the clothing of the accused, and also on that of the alleged victim, spots of pus were found, and handed over for examination to a physician and a pharmacist of the first class. These experts declared the pus to be gonorrhœal, whereupon the defending counsel demanded proof of the presence of

gonococci. Dr. Castiaux, Professor of Forensic Medicine at Lille, was, therefore, called upon to make a fresh examination of the spots with the object of determining the existence or non-existence of micro-organisms. Dr. Lober, who took part in the examination, made pure cultivations of the pus on various media, and finally on sweetened and peptonized agar, and by this means was able to confirm the gonorrhoeal nature of the pus.

NEW YORK.

—The graduating exercises of the Brooklyn Hospital Training School for Nurses were held at Historical Hall, Brooklyn, on the 9th of January, when diplomas were presented to a class of thirteen by ex-Mayor Low, who presided. Addresses were read by the Rev. Dr. Storrs, Judge Van Cott, and Dr. Pain, of the hospital staff.

—The graduating exercises of the Bellevue Hospital Training School for Nurses were held on the 10th. There were twenty-four graduates, and the principal address was made by Dr. Charles Simmons, of the Department of Charities and Correction.

—The annual report of the Department of Vital Statistics of the Brooklyn Board of Health, just made public, shows that there were 17,078 deaths in that city during the year 1887—an annual death-rate of 22.72 for every 1,000 of population. The number of births reported was 12,750, and of marriages, 5,700. The Board of Health estimates the present population of the city at 774,807, an increase of 29,762 during the past year.

—The new Mayor of Brooklyn, Mr. Chapin, has appointed Dr. John Griffin Health Commissioner of the city, in the place of Dr. Otterson. Dr. Griffin is a member of the Kings County Medical Society, and of the Brooklyn Board of Education. He is a native of Ireland, forty-two years old, and came to this country in 1868. While attending lectures at Bellevue Hospital Medical College, of which he is a graduate, he is said to have supported himself by reporting for a morning newspaper.

—In a case occurring in Brooklyn, in which the evidence at the coroner's inquest showed that the death of a two-year-old child was due to arsenical poisoning, the result of taking a prescription in which the drug-clerk who made it up put in more than one hundred times the amount of arsenic ordered by the physician, the jury has rendered a verdict to the effect that the medicine was "accidentally compounded"; and the clerk has been discharged from custody.

—At the last meeting of the Croton Aqueduct Commissioners, a resolution was very properly passed requesting the State Board of Health to prevent the placing of a contemplated cemetery above the aqueduct at a certain point along its route.

—A farmer of West New York, N. J., who was recently arrested, charged with offering for sale in Washington Market the carcass of a cow which had died of pleuro-pneumonia, pleaded guilty when his case was brought to trial, and has been fined \$100.

—At a meeting of the New York Medico-Legal Society, held January 11th, Clark Bell, Esq., who has lately been re-elected President, delivered his inaugural address, and a paper on "Criminal Jurisprudence," by Dr. Bryce, Superintendent of the Alabama Insane Asylum, was read by the Secretary; after which Dr. Feldman, a Russian physician, made some experiments in hypnotism and "mind-reading."

—Mr. Vedder, who recently introduced into the State Senate the bill providing for the placing of the Health Officer of the Port of New York on a salary of \$10,000 per annum, has now introduced another bill reorganizing the Quarantine Commission, and providing that the Presidents of the Boards of Health of New York City and Brooklyn shall be members of the Commission.

—Dr. John Adam Weisse, the distinguished philologist, died January 12th, after a protracted illness. He was born in the province of Lorraine, December 3, 1810, and was graduated in classics at the college in Bitche, and in chemistry and philosophy at the Metz Seminary. He subsequently became Professor of the French language at the Imperial School of Vienna. In 1840 he came to America, and a year later, married at Watertown, Mass., Miss Jane Lee Hunt, who survives him. During his eight years' residence in Boston he published a "Key to the French Language," which was favorably received by Professor Longfellow and other competent judges. He then studied medicine at Brussels, and, after receiving his degree, returned to New York, where he continued to reside up to the time of his death. He built up an excellent medical practice, but found time to pursue the philological studies which had become the favorite occupation of his leisure. In 1878 he published his most important work, "The Origin, Progress, and Destiny of the English Language and Literature," which is said to have won the marked approval of such scholars as Gladstone, Max Müller, Darwin, and Charles Sumner. Some years ago, Dr. Weisse retired from active medical practice, and devoted himself almost entirely to his literary pursuits.

—Up to January 11th, the amount received from the Hospital Saturday and Sunday Collection had reached the handsome sum of \$33,766.

—Dr. C. D. Crothers, of Hartford, editor of the *Journal of Inebriety*, is to deliver two lectures on the "The Disease of Inebriety: its Pathology and Treatment," before the Albany Medical College, January 24th and 25th.

Miscellany.

AXILLARY ADENOPATHY IN THE COURSE OF TUBERCULOSIS OF THE LUNGS.

THE foregoing is the title of an inaugural thesis by Toledo,¹ to which we find reference in the *Archives of Pediatrics*, January, 1888. The question is a new

¹ Le Concours Méd., August 28, 1887.

one to which Graucher recently called attention, exhibiting at one of his clinics a little girl, who, after suffering from pleurisy, entered the hospital and disclosed tuberculous lesions of the lungs and a large glandular tumor in the right axilla. Hypertrophied glands were also found at the level of the supra-clavicular region and the submaxillary region of the same side. Graucher also related two other cases in which the coexistence of tubercular lesions of the lungs and axillary adenopathies had been observed, and showed how the relation of cause and effect could be naturally traced between the pulmonary and the glandular lesions. The tubercular lesion of the lungs may infect the glands in the axilla through the medium of the pleura, either by the direct way of the lymphatics, which go from the thoracic wall to the axilla, or by way of the supra-clavicular glands. This course in the development of tuberculosis has importance in some cases with reference to diagnosis and prognosis. The glandular swelling should call attention to the yet latent pulmonary disease, and to the necessity of its extirpation to prevent the infection, which may then possibly be local, from becoming general. Graucher's advice is, therefore, pertinent, that one should never neglect to explore the axilla of a phthisical person, and that one should never neglect to auscultate the lungs if a tumor in the axilla is found.

POST-MORTEM PARTURITION.

DR. R. TEMPLE WRIGHT, of India, gives in the *Indian Medical Gazette* for October, 1887, the report of a case of the expulsion of a fully developed fetus after death, the mother having been in good health when she committed suicide by drowning. The woman, aged twenty-seven, threw herself into a well, and remained there three days in very hot weather. The body was then removed, and lay, from 8 A.M., all day in the sun, decomposing very rapidly. No-body touched it till 8 P.M., when it was raised to be carried away. Then it was noticed that something was hanging between the legs, which proved to be the fetus, with the inverted uterus. The perineum had given way, rupturing from vagina to rectum, apparently under pressure from the gases developed by decay inside the body, and the uterus, with all its contents, had emerged from the vagina, and was turned inside out. The contents were a full-grown male fetus, with the remains of the membranes, funis, and placenta, all continuous with each other, but detached from the uterus.

No trace could be found of any ligature on the umbilical cord, or of any stick, or rag, or powder, or anything else which could injure the uterus, which had no apparent lesion except the inversion.

The fetus and other structures also showed no sign of injury but decomposition.

Dr. Wright cites similar cases from a number of authors, among them Chevers, who mentions three cases of *post-mortem* birth, all of which occurred in the hot weather in India. In two of them the uterus was inverted. In all of them, however, death had been caused by abortion, at the third, fourth, and fifth month, by pushing into the uterus a twig of *Lall Chitra* (*Plumbago Rosea*). In two of them *post-mortem* birth occurred after the body was placed on

the table in the dead-house, while in the third it happened on the *charpoy* upon which the body was being carried to the Civil Surgeon of Patna, Dr. R. F. Hutchinson, who reports that neither the bearers of the *charpoy*, nor the policeman who went with them, noticed the occurrence of the birth.

Dr. Chevers says the expulsion and inversion of the uterus in his case at Howrah was caused "evidently by the gaseous distension within the body."

In a footnote this author quotes the evidence of the Civil Surgeon of Tirhoot at a trial in 1853. A woman disappeared, and, as she was said to have been murdered, her body was exhumed, and at the necropsy the body was much decomposed, the uterus and some intestines being expelled through the vulva, and some other coils of intestine through a rupture in the right side of the abdomen, "forced by the progress of putrefaction (gases in the abdomen)."

Other authors, such as Aveling, Ogston, and Taylor, refer to the occurrence of *post-mortem* parturition as possible, and the matter is certainly one of interest to students of forensic medicine.

THE CONNECTION BETWEEN ERYTHEMA NODOSUM AND RHEUMATISM.

DR. STEPHEN MACKENZIE has tabulated the particulars of one hundred and eight cases of erythema nodosum collected from the records of St. Thomas's, Guy's, St. Bartholomew's, and the London Hospital, especially with reference to a combination with rheumatism. (*Clin. Soc. Trans.* XIX, 215.) The *Journal of Cutaneous and Genito-Urinary Diseases* thus summarizes the results of his investigations:

He found in thirteen cases acute, and in four sub-acute rheumatism recorded as co-existing with erythema.

In seventeen other cases, joint pains, apparently of a rheumatic character, were present. In three of these cases there was a history of previous rheumatism, and in four, evidence of heart disease, in two "sore throat," and in two a family history of rheumatism. Thus, if it be assumed that these seventeen cases were all rheumatic, there would be 34, or 31.4 per cent. in which E. nodosum was associated with some kind of rheumatic affection.

In twelve other cases the patient was said to have previously suffered from rheumatism. In eleven other cases there was what was called a family history (but this of almost no value in the case of ignorant patients).

In ten cases a cardiac murmur without history of rheumatism was present: and in five besides these, murmurs apparently due to endocarditis came on during the attack of erythema.

The general conclusions were:

(1) "That E. nodosum is frequently associated with definitely rheumatic symptoms, for example, arthritis, sour sweats, sore throat, etc."

(2) "That heart disease (endocarditis) may arise during an attack of E. nodosum, with or without joint inflammation."

(3) "These conclusions justify the inference that E. nodosum is frequently, if not generally, an expression of rheumatism, even when no definitely rheumatic symptoms are present."

Correspondence.

CHILDREN'S PERIODICALS.

BALDWINVILLE, January 7, 1888.

MR. EDITOR, — After reading "Sour Milk for Babies" in the *Journal* of November 17th, I am encouraged to report a similar outrage in the advertising columns of a youth's paper. The matter was called to my attention by finding in the possession of a boy under my care the circulars which I enclose to you. This boy is unusually bright, but in his reading, like many imaginative children, turns everything to a gratification of an abnormal love for facts and names relating to sexual matters. It seems as if the paper in question would not advertise such a scheme if it knew just the nature of it. Perhaps it would be more generous to inform them, instead of you, of the bad character of this advertisement, but it surely can do no harm to add my voice to the one already heard through your paper, to

bring out the fact that wrong things do creep into the children's papers. Very respectfully,

E. F., M.D.

— A dispute has lately arisen in Paris between M. Zola and M. Sarcy over the question whether asses can vomit. The former writer, in his pursuit of realism, thought it well and appropriate, in his latest work, "La Terre," to represent an ass as becoming intoxicated, and went on to describe the animal's acts of vomiting. The critic pronounced this as against nature, and quoted a veterinary to the effect that the act of vomiting in the ass was impossible from the structure of the stomach. Zola retorted, that before writing the chapter he had read up the subject, and he cited good authorities that asses and horses, while they rarely vomited, could, and actually did sometimes do so.

REPORTED MORTALITY FOR THE WEEK ENDING JANUARY 7, 1887.

Deaths reported 1,795: under five years of age 626; principal infectious diseases (small-pox, measles, diphtheria and croup, diarrheal diseases, whooping-cough, erysipelas and fevers) 308, acute lung diseases 333, consumption 198, diphtheria and croup, 139, scarlet fever 51, typhoid fever 23, diarrheal diseases 26, measles 19, whooping-cough 13, malarial fever 14, cerebro-spinal meningitis nine, erysipelas seven, puerperal fever seven. From diarrheal diseases, New Orleans 11, New York seven, Baltimore and District of Columbia two each, Boston, Pittsburgh, Charleston and Fall River one each. From measles, New York seven, District of Columbia six, Baltimore five, Fitchburg one. From malarial fever New Orleans five, New York four, Baltimore and Springfield two each, Somerville one. From whooping-cough, New York five, Boston and Milwaukee two each, Baltimore, District of Columbia, Pittsburgh and Cambridge one each. From cerebro-spinal meningitis, New

York and Lynn three each, Milwaukee two, Fall River one. From erysipelas New York and Boston three each, Newton one. From puerperal fever, New Orleans four, Pittsburgh three.

In the 28 greater towns of England and Wales with an estimated population of 9,244,069, for the week ending December 24th, the death-rate was 20.8. Deaths reported 3,674; infants under one year of age 818; acute diseases of the respiratory organs (London) 337, whooping-cough 145, scarlet fever 91, measles 79, diphtheria 47, fever 47, diarrhoea 23, small-pox (Sheffield 21, Bristol two) 23.

The death-rates ranged from 15.5 in Derby to 31.7 in Blackburn; Birmingham 21.6; Bradford 19.1; Bristol 22.4; Hull 19.3; Leeds 16.5; Leicester 31.3; Liverpool 20.3; London 18.6; Manchester 28.9; Nottingham 19.3; Sheffield 23.9; Sunderland 23.3.

In Edinburgh 21.2; Glasgow 23.5; Dublin 29.4.

The meteorological record for the week ending January 7, in Boston, was as follows, according to observations furnished by Sergeant O. B. Cole, of the United States Signal Corps:—

Week ending Saturday, Jan. 7, 1887.	Barom- eter.	Thermometer.				Relative Humidity.			Direction of Wind.			Velocity of Wind.			State of Weather. ¹			Rainfall.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JANUARY 7, 1888, TO JANUARY 13, 1888.

TUSON, LOUIS S., captain and assistant surgeon. Relieved from duty at Headquarters, Division of the Missouri, and as examiner of recruits at Chicago, Illinois, and ordered for duty as post-surgeon at Watervliet Arsenal, New York, relieving Capt. Henry G. Burton, assistant surgeon. S. O. 5, A. G. O., January 7, 1888.

BARNETT, RICHARDS, captain and assistant surgeon. Ordered from further duty in Division of the Atlantic, to duty at Fort Eley, Kansas, to take effect at the expiration of his present sick leave. S. O. 5, A. G. O., January 7, 1888.

APPEL, A. H., captain and assistant surgeon. Granted leave of absence for twenty days. S. O. 1, Department of the Missouri, January 3, 1888.

BANISTER, WM. B., first lieutenant and assistant surgeon. Ordered from Fort Lowell, Arizona, to Fort Wingate, New Mexico. S. O. 3, A. G. O., January 5, 1888.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE UNITED STATES MARINE-HOSPITAL SERVICE, FOR THE WEEK ENDING JANUARY 7, 1888.

MURRAY, R. D., surgeon. On being relieved at Ship Island, Miss., to proceed to Key West, Fla., and assume charge of the service. January 4, 1888.

DEVAN, S. C., passed assistant surgeon. Relieved from duty at Port Townsend, Washington Territory, to assume charge of Sapelo Quarantine. January 5, 1888.

GLENNAN, A. H., passed assistant surgeon. Relieved from duty at Key West, Florida, to assume charge of the service at Port Townsend, Washington Territory. January 5, 1888.

CARRINGTON, P. M., assistant surgeon. Promoted and appointed passed assistant surgeon from January 20, 1888. January 7, 1888.

SOCIETY NOTICES.

MASSACHUSETTS MEDICAL SOCIETY, SUFFOLK DISTRICT.—THE SECTION FOR MEDICAL MEDICINE, PATHOLOGY AND HYGIENE. Special meeting. By invitation of Prof. F. W. Farham, a special meeting of the Section will be held in the building of the Peabody Museum, Harvard University, Cambridge, on January 25, 1888, at 7.45 o'clock. Professor Peabody will describe the recent explorations carried out under his direction in the Serpent Mounds, and exhibit and explain the important relics there discovered. All members of the Massachusetts Medical Society are cordially invited to be present. The Peabody Museum is on Divinity Avenue. Leave the cars at Quincy Street.

A. L. MASON, M.D., *Chairman*.

ALBERT N. BLODGETT, M.D., *Secretary*.

MASSACHUSETTS MEDICAL SOCIETY, SUFFOLK DISTRICT.—SECTION FOR OBSTETRICS AND GYNECOLOGY. This Section will meet at 19 Boylston Street, on Thursday, January 20th, at 7.45 o'clock. Dr. John Homans will report a case "Of Semi-solid Ovarian Tumor mistaken for a Uterine Fibroid; Ovariectomy; Recovery." "A Case of Successful Removal of a Large Uterine Fibroid by Laparotomy." Dr. E. W. Cushing will report a case of "Supposed Tubal Pregnancy; Rupture; Recov-

ery." The discussion will be opened by Drs. R. H. Fitz, John Homans and J. P. Reynolds.

J. W. FARLOW, M.D., *Chairman*.

GEORGE HAYEN, M.D., *Secretary*.

"The Pinckney."

MEDICAL SOCIETY OF THE STATE OF NEW YORK.—This Society will hold its eighty-second annual meeting at Albany, on the 7th, 8th, and 9th of February, 1888.

OBITUARY. REV. PETER PARKER, M.D.,

Died at Washington, D. C., January 10, 1888, aged eighty-three. Dr. Parker was a graduate of the Medical Department of Yale College, and was elected an honorary member of the Massachusetts Medical Society in 1861. His presence at the annual meeting of the Society about ten years since, soon after his return from China, will be remembered by all who were present and listened to his interesting account of his work as a Medical Missionary in China. Dr. Parker devoted the best part of his life to mission work in China.

Dr. Lowe, in his recent work on Medical Missions, says of Dr. Parker, "This pioneer of Medical Missionary work arrived in China in 1834, and established a hospital at Canton, which soon became so popular, that patients of all ranks, and from distant parts of the country flocked to it."

On his return to America in 1831, he visited Edinburgh, where he was the guest of Dr. Abercrombie, and the result of his visit there was the formation of the Edinburgh Medical Missionary Society. On his arrival in Boston, early in 1841, a meeting of the Boston Medical Association welcomed him, and after commending his work in a series of resolutions, appointed a committee consisting of Drs. Jackson, Warren, Shattuck, Hooper and Bowditch, who soon raised the sum of \$5,000 in aid of Dr. Parker's medical work in China.

In 1845, he was appointed by the United States Government secretary of legation and Chinese interpreter, and some ten years afterwards was appointed United States Commissioner to revise the treaty of 1844.

Dr. Parker was specially noted for his skill, in general, and in ophthalmic surgery, and the reports of his operations, as published in the *Chinese Repository*, a journal published in the English language at Canton, compare very favorably with modern reports of the same nature.

APPOINTMENTS AT THE CARNEY HOSPITAL.

The following appointments have been made at the Carney Hospital: Dr. George G. Sears, registrar; Dr. E. K. Dunham, pathologist.

ERRATUM.

DEATH.

Died at Washington, D. C., January 10, 1888, Peter Parker, M.D., M.M.S.S., Hon., aged eighty-three years.

BOOKS AND PAMPHLETS RECEIVED.

Forensic Surgery. Wm. Zuppan vs. Wm. Dickinson, M.D. Verdict for defendant. John D. Johnson, Esq., counsel.

Address.

PROFESSIONAL REMINISCENCES.¹

BY BENJAMIN EDDY COOTING, M.D., ETC.

THE local semi-social association, the "Roxbury Society for Medical Improvement," has had from the start my earnest efforts, and whatever I could do for its interests and prosperity.

And further, I am the only surviving member of the committee appointed to organize this, the Norfolk District Medical Society, in 1850. Its early developments were not fully satisfactory. Social meetings having been suggested to increase good fellowship, to bring out greater numbers and to excite them to extra work, I was the first to have such meetings at my house; and subsequently there were many more such at the same place, with best results.

For a long while this Society was noted for the social and friendly relations of its members, among whom, from the first, were as high-minded and true men—able and experienced—as ever belonged to the profession. It was a pleasure and privilege to be associated with them. I cannot withhold an instance of the amenities of times alluded to. The late Dr. Monroe, Sr., was always my opponent in Society discussions—and naturally so, being as he was, originally, of the most "heroic" school.

Once hearing that I was to read a paper, he rose from a sick bed, came to the meeting (where he was obliged to lie upon a sofa), and earnestly assailed my positions. After adjournment he called me to his side, said that he was ill, and wished my diagnosis and advice. I took him in my chaise to my own house, where he remained several days. During this time I examined his case, gave him my opinion, and my advice which he promised to follow.

In illustration of our contention: Dr. Monroe always declared that membranous croup could be "broken up" without failure, by heavy doses of sub-sulphate of mercury; that, with this remedy, he never lost a case in that disease. I, on the contrary, maintained that it was a self-limited disease, especially dangerous by its local affection; that, when recovered from, it was through the normal separation of the peculiar membrane; that the inhalation of soothing vapors was most likely to bring on a favorable issue, while more humane in any event; and in such discussions as ours, no case should be cited, unless the characteristic tubular membrane had been secured, before or after death. To which he would rejoin that the sub-sulphate arrested any such formation or tendency to it, and therefore he could not exhibit a membrane as I had done. I again answered that the drug had never had this effect in any case where I had seen it tried; and that I could only say that probably, by some fortunate chance, the real disease had not appeared in his circuit, for I had known of its absence from places for a long time, to return and prevail again without known reasons.² If it had been in his town, I thought, cases must have occurred wherein the membrane had formed before he had been called

to the patient, the disease often being so insidious as not to be recognized until danger from the membrane is imminent. For example, I once gained greater reputation for predicting a fatal result than in any successful case of the kind. The child was called in from its play in snow-slop in the street. The disease was found fully developed; but my opinion that there was hourly danger was indignantly scouted by the bystanders. The child died before the next morning; and for years, I was pointed out by amazed attestants as *the man who said the child would die!*

Thus we argued, earnestly but without offence. We could differ radically on professional questions without personal estrangement.

At one time this Society was one of the foremost in the State in active and good work and its example roused other societies from their lethargy.

It is now looking up again; and, under its present able and efficient officers, and its intelligent and aggressive leader, permeated with the new and fresher blood of its recent acquisitions, bids fair to regain its old position among the District Societies, and to be a source of usefulness to the profession and the public, as well as to its members.

The social reunion to follow this meeting is a proof, perhaps the last one I can give, of my continued belief in the real utility of mingling pleasant with useful things, even at meetings for the advancement of science.

How it happened that I should get involved in so many of these and such like professional matters outside of my personal routine work, I cannot, I must repeat, even now comprehend. It certainly was not of my own seeking. Much of it was foreign to my personal instincts and private interests. No selfish motive could ever have induced it. I had all the practice I wanted. The labor required, turned to personal ends, would have greatly increased my acquisitions; the time taken could have been occupied with far more congenial matters; and the money spent, from my own *earnings* solely, (literally, from first to last, more than "tithes of all I possess.") would be a very desirable addition to the little I have been able to accumulate for the shutting-in clouds of life.

I sought no place, but whenever duties were imposed on me I have endeavored with earnest effort to perform them. If any good has resulted, that is a satisfaction. If not, the intention and the effort were there all the same.

In a former part of this paper I told of my studies in the natural history of disease, and how it was shown that, disease having a beginning, middle and ending of its own, medication, however useful it might be, was not essential for restoration to health. I have myself been through several severe attacks without resort to drugs. A few years ago, during an unusual prevalence and fatality of the disease, I passed safely through a desperate attack of acute pneumonia without a particle of medicine of any kind, to the anxious apprehension of attendants, who thought all was over with me on that account. Even in occasional delirium my wishes were complied with in respect to medication. Convalescence was as speedy and perfect as it ever is, and no vestige of disease has remained.

With such experiences, strange as it may seem, I have a stronger faith in drugs than in my earlier days—in their proper places. Their proper places, how-

¹ Read, in part, before the Norfolk District Medical Society, October 25, 1887. Concluded from page 62.

² I can now add, as a curious fact, that in my own neighborhood where I have formerly known it to occur at the same time in several families, and several cases in a single family, there has been for years little or no membranous croup, some prominent practitioners not yet having seen a case of it here. Of a truth the migrations of disease are beyond our ken.

ever, are not in "breaking up" disease, or in continuous administration during its usual course.

It will be a happy day for patients, to say nothing of the true physician, when the medical attendant can unreservedly speak to confiding and obedient listeners, the solemn truths of his profession in regard to its limitations. Invaluable and indispensable as the profession is and always will be to individuals and the community, its worth rests on far different foundations than a capacity for dosing. In this respect I cannot forbear re-quoting the words of Dr. Moore (the father of Sir John, the hero of Corunna), as true now and ever will be as when uttered a hundred years ago: "The difference between a good physician and a bad one is certainly very great; but the difference between a good physician and no physician at all, in many cases, is very little" — a truth worthy of all acceptance. A good physician, often seeing that his patient will be as well, if not better, without medicine, will, regardless of outside pressure however great, wisely withhold it. "Fools rush in" is a fraction of a favorite quotation of an old professional friend, which at the present time I forbear to complete.

I have myself proved, to my own satisfaction at least, that drugs are no more requisite for the "cure" of disease than splints are for the healing of fractured bones. Both may be of greatest service, but neither are absolutely necessary, and on neither does recovery actually depend. I have successfully treated many hundreds of cases of disease without drugs, and a few fractures without splints. One of the most satisfactory results of a fractured clavicle in an adult was so treated, and I have seen results quite as good as after best attention and care, in a case of smashed-up elbow (condyles, olecranon and all), when undesirably left to itself, unsupported after first adjustment. This is no argument against splints, or drugs even, but shows only that they, while useful, are not necessarily essential.

Nature indeed restores the sick and the injured, but the physician should "cure" the patient by taking the most judicious *care* of him. For the present, and, if "indications" are of any worth, for some time to come, the physician's *duty* will chiefly consist in restraining his own and people's tendency to over-dosing, and perturbing interferences. It is truly a pity that the ill should have to endure so much more than their ailments, from the hands of mistaken kindness.

The inordinate use of quinine affords a good illustration. Its reputed power to "jugulate" intermittent fever has induced its almost universal use for all manner of diseases, especially where any periodicity can be attributed to the ailment, or any "malaria," so-called, suspected, however irrational such supposition may be. The evil thus done can hardly be over-estimated.

It may be doubted even, speaking not without knowledge thereof, whether the "quininism," or "quininitis," thus engendered, worse sometimes than the original disease itself uninterfered with, may not more than overbalance any "jugulation" ever actually effected, so recklessly has the drug been used.

Moreover, its reputation as a "specific" has led to an amount of harmful experimentations in the hope of finding "specifics" for other diseases, that is painful to contemplate. Possibly more mischief has resulted from this source than all the good achieved by

the drug, even taking the estimation of its most ardent advocates.

More than three million (3,000,000) ounces of quinine were consumed in the United States alone last year (1886), and the amount used is greatly on the increase. What if it were all of standard quality and strength!

But the popular idea of a physician, and the necessity of drugs, even in the profession itself, is far different from that we advocate. Most people regard a doctor, especially their own attendant, skilful, if a ready doser, one who can hit upon the right medicine even without examining the patient. More than once have I, in case of supposed urgency, to satisfy an eager demand for it, sent a remedy (a harmless one of course), ahead by the messenger, and, on my arrival, found friends assiduously administering it. This before I had seen the patient or had any adequate idea of his malady. Think for a moment how unwise their so doing; and yet these people were accounted among the most intelligent in the community!⁸ On the other hand, and not a solitary instance, a well-to-do patient has objected to his bill, saying: "No doubt you have made the visits, but only on three or four occasions did you write a recipe. I am willing to pay for those, but not for visits when you did nothing."

Many persons like to have their ailments magnified, as though it were a meritorious distinction, but in attendance upon my patients, whether rich or poor, I have always endeavored to render their calamity (for sickness *is a calamity* and nothing else), as little dispiriting and otherwise burdensome as possible. I was never an alarmist. Having an eye to the possibilities of the situation, I have made everything as quiet as possible with as little disturbance to family routine, and, I may add, with as little expense⁴ as circumstances permitted. Sanitation, so-called, has not been neglected — guided not by rules, often absurd in given cases, but by what little common sense I possessed, and by the possibilities of improving the surroundings of the case. As to the patient himself, I have sought his *best* treatment as a *sick man* rather than as a man sick of a nominated disease. Depending less on routine prescriptions than on general rational management, I have of course been guided by the best diagnosis of the case obtainable by myself, or others when assistance seemed requisite. Still I have always, regardless of pecuniary or personal consequences, withheld drugs as far as *possible*, as I would wish done in my own case in like circumstances. This having been generally understood from my start in practice, has deprived me of the patronage of a number, who said that when they were sick they *knew* that they needed *medicine*, but if they sent for me they were not sure to get it.

Nevertheless, as new medicines and methods have been suggested, I have tried them as opportunity offered, in order that I might not be rightfully charged

⁴ I have always tried to impress upon my patients that it is better to wait and do nothing than to administer medicines in ignorance of their nature and of the nature of the disease, often quoting the saying of Presb. Kirkland, H. C., that "when you know not what to do, take care that you do you know not what."

⁸ More than one subsequently paying family has recently told me that had I exacted payment of them in their early struggles and first years of sickness they could never have risen out of their poverty. And these were never considered "poor people." Nor is such experience peculiar to one neighborhood. It is related of a notable family by one of themselves "our circumstances have been such that the increase of expense which would necessarily have attended upon the sickness of any one of us might have reduced us to real distress." Cabot's memoir of Emerson, 1887, vol. I, p. 28.

with ignorance or unreasonable doubt of their value. In reviewing my cases I find no cause to regret omission. I wish I could conscientiously say the same of professional commission. May I not charge some of the latter to the irresistible tendency of the times?

General office practice I have always avoided, wishing my house to be my home, a private residence, as much as possible. I never had office hours.

Practice as a consultant I never inclined to, being, constitutionally, in a great measure unfitted for it. It has cost me more for consultations than I have ever received from them. After a consultation I have too often lost the patient; sometimes to the consultant, who should *never* take a case in such circumstances! Autopsies in my circuit, when paid for, have been usually paid for by myself.

Having known much of the profession from very early youth upwards, with a somewhat clear apprehension of its responsibilities and difficulties, its perplexities and trials, I entered it in the laudable hope of gaining an honest and reasonable livelihood, and of being able to render adequate service in return. I do not remember that I specially considered, as some pretend to, the profession as one to "do the most good in." I diligently labored to be able to do "*well*" (as my first patient expressed it) the duty of a good "family physician" in the full sense of the term, as then understood — a term almost without meaning at the present day. Further than that no definite purpose entered into my anticipations; certainly no ambition, or thought even, for place or position. If either of these have fallen to my lot, a more selfish temperament would have saved me from yielding to others' wishes and accepting them. Position could give nothing but discomfort to one of my disposition; my professional work was enough, and more than enough, to occupy all my time. I had nothing personal to gain by taking office, but much to lose in case of unsatisfactory discharge of its duties. I have no apologies, however, for self-forgetfulness in these matters; let others take warning and do better.

As a result, I have no complaint to make against the world, professionally or personally, having deliberately determined, in whatever state therein to be content. If any have differed from me, or taken offence, they have been allowed to go their own way unmolested. I have seldom, if ever, stopped to notice abusive words or acts, to which all in a really active life in every profession are more or less subject. Fortunately, very few such have ever come to my hearing; and those have fallen generally upon deaf ears.

In my dealings with professional brethren, as well as others, I have always striven to ignore any such neighborly tendency in human beings, and have especially endeavored not to allow the possibility of anything of the kind to have influence in any public or private act of mine. The medical profession, through its constant contact with misery and affliction, naturally tends to moderate personal estimation and to assuage personal griefs. What are such trifles to the actual trials of the wretched? Its members are often unjustly reproached as over-sensitive and quarrelsome. There may be such ill-constituted mortals in it (they are everywhere), but the truth is, no other calling engenders so much fraternal respect among its members, or can show more numerous instances of enduring friendship — in my own case it has enhanced one which has lasted from *infancy*, now so many years.

"Who shall decide when doctors disagree," was originally said of casuists, not of medical men.

The profession demands of its members, throughout their whole career, a cheerful willingness to devote more than half their time and labor to the fitful needs of illness and penury, without thanks or hope of pecuniary reward. It even expects them to become, as it were, upper servants to the rich, and attendants of all-work to the helpless poor. It is a calling often to be tired *by*, but never to be tired *of*. It offers little promise to seekers of personal ease, or expectants of large possessions. Nevertheless, its compensations are neither few nor small; and its brotherhood is not among the least of these.

Quæcum ita sint — in spite of the initial famine incident to the profession, and the inevitably slow advancement in it — a patient's confidence, as said an eminent professor, being the hardest thing to acquire, and the easiest thing to lose;⁵ in spite of its privations and hard work, in spite of its annoyances and trials, in spite of its reputed jealousies and quarrelsome habits (which, after much and long observation, I can confidently aver are much less than among pure scientists and literary men, or in other professions, restrained as medical men are by a reasonable etiquette), in spite of its vexations and unrequited efforts, in spite of its thankless patients and wilful maligners, in spite of defections, when and where least expected, unexplained and unexplainable, in spite of all these drawbacks, so much and so often complained of, but no greater, probably, than in other callings — I am fully persuaded that even the life of a physician is worth living.

In so long and so varied a service, there must have been many and great shortcomings. These doubtless are better known and more fully appreciated by my neighbors than by myself. Thus am I rendered happy in the conviction that any attempt on my part to recount them on the present occasion would be merely a work of complete supererogation.

"A man's life," said the wise man, "is like an arrow shot through the air, leaving no mark"; fortunate, we may add, if it reach the target aimed at, though it hit not the bull's eye.

For myself, the arrow has nearly sped its course. How far short of the target it will have fallen may soon be known;

— *moriturus sum* —

and if, perchance, a professional epitaph be ever sought for — to indicate a life-aim, and to conform more nearly to truth than most such tributes to the dead, let it be:

HE CURED THE SICK WITHOUT DRUGS.

— For a comprehensive, if not quite comprehensive sentence, intended to describe the mental tastes of its subjects, commend to us the following sentence from a western contemporary's obituary notice of a clinical teacher, recently deceased. "All his life he has exercised a vigorous opposition to homœopathy, to alcohol, to tobacco, to tea, coffee, etc." The *cetera* leaves little more to the imagination, but we suppose it includes such things as the mind-cure, onions, street-bands, and again *cetera*.

⁵ I once lost a profitable and apparently devoted family for not seeing the *post-mortem* in a crowded street-car. That he saw me, and did not speak to me, was of no account! My offence was unpardonable, and they were ever after my professional detractors.

THE TREATMENT OF INFLAMMATIONS IN THE REGION OF THE ILEO-CECAL VALVE.

BY M. H. RICHARDSON, M.D.,
Surgeon to the Massachusetts General Hospital.

For the purpose of discussion I have divided the cases of inflammation in the ileo-caecal region into the following classes:

(A) Mild cases.

(1) Where the disease is mild, though acute, and has the usual physical signs, that is, dulness and tenderness in the right iliac region, and recovery follows without the formation of abscess—in other words by resolution of the inflammatory exudation.

(2) Cases which run a mild course and terminate in an abscess in the right iliac fossa shut off from the general peritoneal cavity, accompanied by the usual physical signs.

(B) Severe cases.

(1) Cases which run a violent course in which a general peritonitis follows a perforation of the appendix or cecum without the formation of abscess.

(2) Cases in which the violence of the symptoms is due to abscess involving more or less the general abdominal cavity and which may or may not be detected by physical examination.

For the purposes of a discussion which is limited to the surgical treatment of this condition, I think that the above enumeration covers all the points in question.

In the treatment of the first class of cases it is evident that the great danger to be guarded against is the infection of the general peritoneal cavity, or the sudden change from a partial peritonitis of a very mild type to one of the "foudroyant" variety.

The following cases illustrate these two classes:

(A) Mild type. Resolution, or abscess without obstruction or other violent symptoms.

CASE I. L. E., male, aged forty-five, seen by me June 8, 1886. A few days before he had been suddenly seized with pain after a supper of strawberries and lemon pie. Got up and had several loose dejections. The next day was up and about his business. In the same afternoon went to bed with the same general pain he had had before. The pain gradually became localized, and he became able to sit up. Was better and then worse with the pain localized in the right side of the abdomen till the day of my visit, which was five days after the first attack. I found him with a temperature of about 102° in the evening, and with marked dulness and tenderness in the lower part of the abdomen on the right side. He was not suffering very much pain and did not have the appearance of being very ill.

He was advised to have a poultice, opium enough to keep him comfortable, and very cautious feeding. A few days later I saw him again, the attending physician meanwhile keeping the case under careful observation, and found the dulness and resistance decidedly less. A few days after that I saw him again. The pain had disappeared and he was very comfortable. The signs were much less in the right iliac fossa, and he was entirely convalescent. He made a rapid and complete recovery and has had up to the present time, no return of the trouble.

CASE II. Male, aged thirty, was taken with pain in the right iliac fossa, October 9, 1886, after lifting some heavy boxes. It was thought by the attending physician that he had ruptured himself in lifting. Nothing was noticed at the time of the alleged accident, except that he felt for some hours after languid and listless. On Thursday following the Saturday upon which he first had his pain he came down stairs, and the next day went into Boston and out to Cambridge. In the meantime he had been confined to the house. The following day, Friday, he was down sick again, with pain in the right iliac fossa. He had some fever and required morphia subcutaneously. The history as given by the patient was "that he was lifting heavy boxes some time Friday between four and seven in the afternoon." He felt no special trouble except languor quite soon afterwards. He did nothing but went and sat down, saying he felt tired out. Never had anything of the kind before. At the time of my examination which was about a week after the alleged accident, I found him in bed with a morning temperature of 102.5° and a pulse of 100. He had the appearance of being quite ill, and evidently suffering considerable pain. In the right iliac fossa there was marked dulness on percussion with increased resistance and much tenderness. There was no marks of external violence.

I next saw him November 26, 1886. He said he had been out about two weeks. After my visit he remained about the same for some time. Then he began gradually to get better. The pain slowly disappeared but the tenderness remained about the same. The physical signs had disappeared. I was at that time of the same opinion as at first, and as I am now, that he had an inflammation in the region of the ilio-cecal valve without abscess, and with a partial peritonitis.

In the treatment of cases like the above, it seems to me that the most important thing is to watch the patient very carefully and to be ready at any moment to meet a possible extension of the peritonitis, or the formation of an abscess, by surgical measures. I do not suppose there will be any difference of opinion that in such cases there should be no exploratory or radical operation advised unless the symptoms should suddenly indicate that the general cavity of the abdomen had become invaded either by the extension of an already-existing peritonitis, or by the rupture of an abscess hitherto concealed. The case would then become one of the second class or violent cases, the treatment of which will be considered later.

If resolution does not take place, an abscess may be formed which should be opened as soon as discovered, as in the following cases.

(2) Mild course, with formation of abscess in the right iliac fossa, with the usual signs.

CASE III. Eli Trahan, aged fifty-two, sea-captain, entered the Massachusetts General Hospital, Saturday, September 3, 1887, with the following history. Always well and strong. Sailed from Nova Scotia nine days ago. His bunk was occupied and he slept stretched out on some boards. He woke with the sensation of having strained his stomach. Felt severe pain all day. The pain was located in the right iliac fossa. Although his bowels had been regular he thought it necessary to physic himself, and accordingly took salts and castor oil, producing very free catharsis. The pain, however, continued and he noticed

¹ Read at the meeting of the Surgical Section of the Suffolk District Medical Society, December 7, 1887.

that it was very tender in the region of the pain. Two or three days ago he noticed a swelling in the right iliac fossa. It was very tender. There was no chill.

He is a stout and healthy-looking man. Walks without difficulty. In the right iliac fossa there was an indurated mass reaching from the middle point of Poupart's ligament up to the level of the iliac crest. Inwards it extended a little more than half way to the median line. It was very tender, dull and fluctuating.

Operation under ether. An incision was made three inches in length parallel to Poupart's ligament, and between the ilium and the tumor. The dissection was prosecuted along the outer margin of the mass, and the peritoneum was lifted with the finger so that the under surface of the tumor could be reached. By means of a needle the abscess cavity was found and evacuated. The opening was enlarged and eight ounces of very fetid pus removed. The odor was distinctly fecal. A drainage-tube was inserted, and the wound partly closed with silk.

Antiseptic dressings. The next day he was very comfortable, and the discharge abundant. Cavity was syringed with dilute solution of corrosive sublimate. The second day there was abdominal pain, with rumbling of gas, but nothing passed the sphincter. There was very little abdominal tenderness or distension. In the region of the wound there was a little tenderness. During the following week he did uninterruptedly well. A week after the operation there was neither pain or tenderness. The induration was almost entirely gone. Discharge very slight; tube removed. September 15th he was discharged.

October 24th he was seen again at my office. He reported himself as perfectly well.

CASE IV. E. C., aged thirty-four, laborer. Entered the Massachusetts General Hospital October 13, 1887. Family and personal history, as far as could be learned, was unobjectionable. Is so stupid as to be unable to give any clear history of his present trouble. Said he had had a bunch in the region of the right groin for two weeks. That it had been painless, and not associated with any disturbance of the bowels. It had increased slowly in size. He could be made to say almost anything by asking him leading questions. On physical examination a swelling was found in the right iliac fossa, just above Poupart's ligament. It was tense, fluctuating, and not tender. The surrounding induration nearly filled the iliac fossa. He was examined by Dr. Fitz, who made a diagnosis of appendicitis.

Operation. An incision was made over the swelling near Poupart's ligament through the abdominal wall. A large quantity of thick odorless pus was evacuated. Exploration of the cavity with the finger failed to reveal its origin. It extended straight back through the iliac fascia to the sacro-iliac synchondrosis. No diseased bone was felt. It had been thought that this might be a case of abscess dependent upon diseased bone in that region. There was no evidence, however, that such was the case. A large drainage-tube was inserted, and antiseptic dressings applied. During the following week he improved rapidly. The tube was slowly pushed out of the wound, which was washed out daily with a weak solution of bichloride.

October 25th he was discharged with the wound still unhealed. A short time later he was seen by me and the wound found to be entirely healed. I came

to the conclusion that this was a case of abscess originating in the ilio-cecal region, and not connected with disease of the bone.

In the above cases I think there will be no difference of opinion that the treatment adopted was the best for all similar ones. The abscess cavity was opened from below, as far as possible from the peritoneal cavity. The incision was that made for ligation of the common iliac artery, and in the event of finding no pus, or of evacuating it, there was no possibility of contaminating the healthy peritoneum. In this class of cases, however, we must bear in mind the possibility of a general peritoneal infection, and the abscess should be opened as soon as it is discovered. The question here arises, it seems to me, whether we ought ever to make the abdominal incision, in cases like the first two, *before* there is evidence of a general infection of the peritoneum, or, in other words, for the purpose of preventing such infection. It is certainly not wise to interfere where there is little constitutional disturbance, and where there is good reason to think that resolution may take place. The conclusion to which I have come in regard to this point is that the patient should be watched with the greatest care, and, as soon as it seems probable that an abscess is forming, to explore by the post-peritoneal method, and evacuate if any pus is found. By this method there is very little, if any, danger of doing harm. It is, however, within the bounds of possibility that the latent inflammatory process should suddenly develop into a violent general peritonitis, either by the escape of faeces or pus into the general cavity of the abdomen. This event would be marked by the most violent symptoms, and the diagnosis would be easy. But it is just this accident which we wish to avoid, and to the avoidance of which all our efforts should be directed. It seems to me a fair question which has not been as yet solved, as to when it is our duty to interfere in mild cases in order to prevent their becoming severe. In the present state of our knowledge, as it seems to me, no rule can be laid down as to this point. Each case must be judged on its own merits. If the surgeon watches his case with the greatest care, and is ready at any moment to interfere, it seems to me best to wait a reasonable time for resolution, and then make the post-peritoneal exploration. I think it may be said that in neither of the classes of cases already considered is it ever justifiable to make any incision that opens the general abdominal cavity. It is only in the following class of violent cases that laparotomy is ever justifiable, and even in many of them I am of the opinion that a post-peritoneal exploration should first be done.

(B) Violent cases.

CASE V. H. K., aged fifty-five. Had had an attack of stoppage of the bowels about six months before. This continued some days, and was accompanied by great pain and distension of the abdomen. After the use of various remedies there was a free discharge from the bowels, and his recovery was rapid. About the 18th of August, 1887, he was seized with a violent pain, not especially localized at first, with distension of the abdomen, and complete inability to get anything through, either faeces or gas. Temperature was moderately elevated. Pulse was good, ranging about 100.

August 19th I saw him for the first time. On physical examination nothing was found except great distension of the abdomen, with general tenderness.

The pain was general also, with some tendency to localization in the right iliac region. It was impossible to make out a diagnosis with accuracy. It was thought, both by the attending physician, Dr. Cilley, and myself, that the case might be one of general peritonitis, with perforation of the appendix. At the same time the history of an attack precisely similar with complete relief after an evacuation of the bowels, caused an unduly favorable prognosis, and delayed till too late the question of operation.

The distension continued, however, and also the pain. The question of laparotomy was then considered seriously, and the occasion for its performance seemed to have arisen. There was great distension of the abdomen, an evident general peritonitis, and pain more distinctly localized in the region of the appendix. While we were considering the question of an operation he had a very abundant discharge from the bowels, and he seemed so much better that no operation was thought necessary. We were, however, much deceived in the gravity of the case, for that same night he collapsed and died.

At the autopsy, six hours after death, the vermiform appendix was found to have been perforated, and there was a general septic peritonitis, with the usual collections of pus and exudation. The appendix contained a small concretion, which had evidently been the cause of the whole trouble.

In this case it is evident, in the light of the autopsy, that the operation of laparotomy, with excision of the appendix, ought to have been done at the outset. It is also evident that nothing could have been accomplished by the so-called post-peritoneal exploration. In this case there were violent symptoms, prominent among which was obstruction, an evident peritonitis, and very severe constitutional symptoms. There were no physical signs to guide either in diagnosis or in treatment. By physical signs, I mean signs of localization of the peritoneal inflammation.

It seems to me that this is a distinct type of case, and that the indication is perfectly clear. The existence of a general peritonitis with obstructive symptoms means that a laparotomy must be done, and there is no use in any preliminary explorations, for the reason that it adds to the time and to the danger.

I do not think there will be any difference of opinion in a case like the above. The difficulty, however, is to be sure enough of your diagnosis to exclude abscess. It is taken for granted that an abscess should be evacuated post-peritoneally if possible, and that there is very great danger in the evacuation of one of these abscess-cavities through the intestines.

The point of the greatest importance in deciding between a laparotomy and an exploratory incision is the existence of a general peritoneal infection. If there is a great distension of the abdomen, vomiting, great constitutional disturbance—if, in other words, it is one of the desperate cases of this disease—it seems to me that we have to consider only the drainage of a peritonitis and removal of the cause. It is certainly true that a large proportion of the fatal cases of appendicitis are cases of perforation and fecal extravasation, for which the only remedy is laparotomy. It seems also, as Fitz has said,² that the diagnosis of such a condition is comparatively easy. If, then, a diagnosis of perforation and peritonitis has been made, the only reason why a laparotomy should not be done

immediately is that we may be sure we have made no mistake by performing the post-peritoneal exploration, and eliminating the possibility of an abscess drainable from behind. But if we should find and thus evacuate the abscess-cavity, we have still the main trouble unrelieved—the general peritonitis.

If the general peritonitis is due to the presence of a collection of pus so deeply placed that its presence cannot be detected before incision, the chances are, as it seems to me, that a laparotomy will have to be done eventually for the purpose of peritoneal drainage, even if the post-peritoneal operation is successful in reaching the abscess-cavity.

It seems to me that we have in the history of the case the most important data for the solution of this question. I take it for granted that no surgeon wishes to open the peritoneal cavity in any of these cases, if the same result can be reached by other means. If, then, we have good reasons for the belief that there is a sudden perforation of the appendix, with immediate lighting of peritoneal inflammation, we have just the case for laparotomy. The history of the case, as it seems to me, furnishes the best reason for the formation of this supposition. The sudden access of a severe pain, increased temperature, and general symptoms of violence to the peritoneum, mean either extravasation of feces or of pus from an abscess previously undiscovered, or, perhaps, unsuspected. This condition of things means laparotomy, first and always.

If, on the other hand, the onset of the symptoms is more or less gradual; if the patient survives, or is about the same, without any extreme symptoms; if there is no evidence of a general infection, then it seems to me that the operation of laparotomy is not justifiable until the preliminary exploration has been made.

In the preparation of this paper, I have been guided largely by the request of the Secretary to devote especial attention to the question of the anatomy of the parts, and the operative steps best adapted to the ends to be attained.

For this purpose I have made a few observations on the cadaver, of which the following is a brief summary. The number of subjects examined was fourteen—a number far too small to draw any very positive conclusions from—at least, in regard to points in which there has been any difference of opinion.

(1) Male. Median incision $3\frac{1}{2}$ inches in length. Appendix found easily. Also found easily by the incision for ligation of the common iliac. The appendix was found lying behind, free, $2\frac{1}{2}$ inches in length, with a mesentery. The cecum had no mesentery, and was only half covered with the peritoneum. The reflexion on the inner side was along the border of the psoas magnus, and outwardly, quite up to the iliac crest. The appendix could be brought to the incision by either method—median lateral, or by the semilunar cut.

(2) Appendix $2\frac{1}{2}$ inches long. Had a mesentery. The base of the appendix, that is, the point of origin from the cecum, was two inches from the crest of the ilium, and $2\frac{1}{2}$ inches from the anterior superior spine. The base of the appendix was one inch from the reflexion of peritoneum over the iliac vessels down into the pelvis. This measurement shows how much the base can be shifted for purposes of operation. It was found, in this case, that the point in the abdomen

²Transactions Am. Med. Association.

directly over the appendix was $4\frac{1}{2}$ inches from the spine of the pubes along the outer border of the *rectus abdominis*.

(3) Appendix sought by the iliac-ligation incision. In this operation there is great difficulty. By the incision along the outer border of the rectus, it was very easy to grasp and lift it out. Length of the appendix, three inches. From the middle of Poupart's ligament to the base of the appendix, $4\frac{1}{2}$ inches. From base to reflexion over iliac vessels, $2\frac{1}{2}$ inches. In this case, it would have been very easy in life to have lifted and removed by almost any incision. It could have been excised with great ease from the median line. From the *linea semilunaris* it was easier than anywhere else. $4\frac{1}{2}$ inches above the spine of the pubes was found to be right over the base of the appendix.

(4) Parts injured by dissector. By median incision appendix not easily found; by semilunar very easily; but $2\frac{1}{2}$ inches long. Has distinct mesentery from ilio-cæcal valve in vertical line. Put on the stretch, the distance of the base from the reflexion is $2\frac{1}{2}$ inches. From the mesenteric line of attachment to the middle of Poupart's ligament, three inches. From spine of the pubes to the point just over the base, $4\frac{1}{2}$ inches. Same point to the anterior superior spine, $3\frac{1}{2}$ inches.

(5) Incision made at outer border of *rectus*, $4\frac{1}{2}$ inches above spine. Through two-inch and three-inch incision, impossible to feel and raise the appendix. Incision enlarged so as to see. Appendix found even then with difficulty, being bound down by adhesions, yet found to be directly under the point of incision. Appendix two inches long and obliterated. In this case, it seems to me an inflammation would have resulted in abscess, if anything, and it would have made its way towards the surface by Poupart's ligament.

(6) Same incision as before. Incision $1\frac{1}{2}$ inches. With two fingers tried to find and bring up the appendix. Found to be impossible even with large incision. Appendix base found directly under the point on the outer border of the rectus, $4\frac{1}{2}$ inches from spine of the pubes. The appendix was found to be adherent by its tip, which extended down into a diverticulum of the peritoneum. This attachment made it impossible to draw the whole appendix up to the wound. From the middle point of the Poupart ligament to the adherent tip $2\frac{1}{2}$ inches. Same distance from the anterior superior spine of the ilium. The cul-de-sac was $2\frac{1}{2}$ inches deep, and admitted two fingers.

(7) Same incision. Appendix not easily found by small cut. Not found by four-inch incision. It was found to be totally adherent and so completely concealed that it was only by persistent dissection that it could be made out at all. It was apparently outside the peritoneal cavity entirely. This may have been due to the adhesive peritonitis. The position of the base as in the others. The difficulty in finding was due to the situation behind the peritoneum.

(8) Same incision. Appendix very easily found, having a mesentery and no adhesions. The appendix was very short and stuck up into the abdominal cavity, one inch in length. Base $2\frac{1}{2}$ inches from the iliac reflexion. $2\frac{1}{2}$ inches from the anterior superior spine of the ilium and three inches from the pubic spine.

(9) Easily found. From spine of pubes $4\frac{1}{2}$ inches.

Anterior superior spine $3\frac{1}{2}$. Peritoneal reflexion over the iliac vessels closely attached to base. Not easily drawn out. Appendix very long and extending to the centre of the promontory of the sacrum. At the base of the appendix there was a cul-de-sac in the parietal peritoneum.

(10) Appendix found easily through an incision in the *linea semilunaris* large enough to admit two fingers. There was a separate mesentery. The base of the appendix was three inches from the centre of Poupart's ligament.

(11) Same incision. Appendix found very easily. Had a separate mesentery and was turned down along the outer border of the psoas. Base of the appendix $3\frac{1}{2}$ inches from the centre of Poupart's ligament and three from the anterior superior spine of the ilium. In this case the attachment to the reflexion over the iliac vessels was so loose, that it was possible to bring the base to the anterior spine, down to the centre of Poupart's ligament and even to the spine of the pubes.

(12) Cæcum free. Appendix easily found by the short semilunar incision. Well-marked mesentery, with appendix free in the abdominal cavity pointing towards the centre of the pelvis. The base of the appendix was four inches from the spine of the pubes. It was impossible to get it from behind through the iliac-ligation incision. This was a very movable cæcum. It was possible easily to lift the ilio-cæcal valve from the pelvis reflexion of the peritoneum at least four inches. It would have been possible to have lifted this appendix out of either of the cuts mentioned.

(14) In this case, the appendix and ilio-cæcal valve were bound down to the brim of the pelvis very closely indeed. The incision was first made parallel to Poupart's ligament, through which the end was found and drawn partly out. The same was done next through the lateral cut and then by the median. It was found as in the other cases, that it was more feasible to remove the appendix by the semilunar cut than by either of the others. The base of the appendix was placed $2\frac{1}{2}$ inches from both the centre of Poupart's ligament and the anterior superior spine. Appendix $2\frac{1}{2}$ inches long.

(14) The same cuts were made in this subject as in the others. The appendix was very loose, indeed, and the tip could be made easily to touch the last rib. It also could be brought to the spine of the pubes and over into the left side of the abdomen.³

The most evident fact established by these dissections is that the best place to open the abdomen for the purpose of finding the appendix vermiformis, is in the left *linea semilunaris* about four inches above the left pubic spine. If a small incision is made at this point the appendix can be grasped with two fingers and brought to the surface in many cases. In all the cases this can be done provided there are no adhesions, and there is no very great distension of the abdominal wall. As this exists, however, in just those cases where it seems to be necessary to open and remove the appendix, we must anticipate considerable

³ Since reading this paper I have made similar observations upon twelve subjects with the same general result. In some cases the base of the appendix has been extremely movable, and the appendix itself in very extraordinary positions. In one case the tip was found resting upon the right kidney, and in another in the region of the sigmoid flexure. There was the same variation as to the mobility of the base. The average case, however, showed that the *semilunaris* incision was the best on the whole.

difficulty in bringing up the appendix to the surface through a small opening. In such cases, where the base of the appendix is bound down by inflammatory adhesions, or where the normal reflexion of the peritoneum covering the appendix is so firm and close as not to permit of any considerable displacement from the iliac vessels, I venture to assert that it will be much less difficult to bring the appendix into the semilunar wound than into either of the others.

There is another reason for the selection of the incision rather than the one near Poupart's ligament. When the appendix is grasped by the latter cut, it is necessary to push the bowels away in order to proceed with the proposed operation. In the median or the semilunar cut, the cecum is pulled towards the cut in such a way as to carry with it the other intestines, leaving a clear space for the subsequent manipulations.

Another point, established, I think, by these dissections, and that is the extreme difficulty found in isolating the appendix after dissecting up the peritoneum in the extra-peritoneal incision. In the normal subject it is extremely difficult to find the appendix in this way, and to subject it to any surgical manipulations, even so simple as tying and cutting off, is incomparably more difficult than in the semilunar incision. Finally, I would say that I was very much surprised in reading the recent admirable article of Dr. Weir,⁴ of New York, on this subject, to see for the first time Treves's statement⁵ as to constant presence of a complete peritoneal covering to the cecum and appendix. In most of the cases observed above where the appendix was not adherent as stated, it was surrounded by peritoneum, but this was not true of the cecum itself, except in a few. In one case, the reflexion of the peritoneum left the parietes at the outer border of the psoas magnus and touched it again at the iliac crest, and in many of the cases the posterior part of the viscus was not covered by at least one-third.

The general conclusions to which I have arrived, are as follows:

(1) In mild cases of inflammation in the region of the appendix there should be no surgical interference till physical examination reveals the presence of an abscess which should be incised by the post-peritoneal method.

(2) In violent cases, where it is evident that there is a general peritonitis, laparotomy should be done immediately, just as soon as a diagnosis of general peritonitis has been made.

(3) In violent cases where it is doubtful whether the general peritoneal cavity has yet been invaded, and where the history and the physical examination favor the presence of an abscess in the ileo-caecal region, though it is impossible to locate the exact seat of the inflammatory process, an exploratory incision should first be made in the right iliac fossa, and the ileo-caecal region explored post-peritoneally.

(4) The best incision to reach the appendix in the average case, is along the outer border of the rectus, about 1½ inches from the spine of the pubes.

(5) The best incision for extra-peritoneal exploration is parallel and close to Poupart's ligament, beginning in about the centre, and extending outwards and backwards a sufficient distance.

PERFORATION OF THE VERMIFORM APPENDIX, CAUSING AN INTRA-PERITONEAL ABSCESS AND GENERAL ADHESIVE PERITONITIS. — LAPAROTOMY AND DRAINAGE. — RECOVERY.¹

BY J. W. ELLIOT, M.D.,
Surgeon to Out-Patients at the Massachusetts General Hospital,
Instructor in Boston Polytechnic.

The patient was a physician in active practice, in the prime of life (thirty-two years) and in perfect health. In the last week of August he had a severe colic lasting three days, and requiring a dose of morphia, and subsequently he had occasional slight pains. He had eaten a great deal of fruit during the autumn, especially grapes.

On the night of October 29th he was attacked by a severe pain in the abdomen, for which he took morphia subcutaneously. On the following morning, October 30th, the pain was extremely severe with purgatives, when chloroform, as well as morphia, was used to give relief. Morphia was given continuously every four to six hours. The seat of pain was between the umbilicus and pubes, extending to the right side, and shooting down into the bladder, penis and testicles, so that it seemed like the passage of a renal calculus. Micturition and defecation were painful and difficult. The evening temperature was 102°. He vomited during the evening.

October 31st. He had diarrhoea, with severe gripes. There was pain and tenderness over the whole abdomen, most marked in the lower part. The colon seemed to be full, but there was no tumor to be felt on the right side. Temperature 102°, pulse 120.

Nov. 1st. The abdomen was more rigid and somewhat distended; the pain in the left iliac fossa was nearly as great as in the right. Micturition became impossible, and a catheter had to be used from that time on. A hot-water injection excited very severe gripping pain. Temperature 102.8°.

November 2d. The abdomen was much more distended. Morphia was given in one-third grain doses.

On November 3d I first saw the patient, with Drs. Cutler and Wood, of Waltham. Although thoroughly under morphia he complained of severe pain and gripes over the entire abdomen, quite as much on the left side as on the right. His mind was wandering, and he was constantly picking at the bedclothes. His features looked pinched. The abdomen was greatly distended, hard, and as tight as a drum. *There was no dullness or tumor to be found.* Examination by rectum gave no positive evidence. Pulse 120. Temperature 101.5°. There was evidently a severe general peritonitis in process.

Dr. Cutler had already made the probable diagnosis of peritonitis, due to appendicitis, and I agreed with him. All the symptoms had become worse within twenty-four hours, and the situation seemed very grave. I thrust a good-sized aspirating needle in different directions into the right iliac fossa, but found no pus. As it was then after dark we decided to attempt nothing further that night.

November 4th. The patient had a poor night, with nausea, retching and vomiting. He also had had symptoms of collapse, with sub-normal temperature. Drs. Fitz and M. H. Richardson were called in consultation. The diagnosis of appendicitis was confirmed. The prognosis was considered unfavorable.

⁴ Medical Record, June 11, 1887, p. 632.

⁵ British Medical Journal, 1885.

¹ Read at the Surgical Section of the Suffolk District Med. Soc. Dec. 7, 1887.

Exploratory laparotomy was decided on as giving the best, if not the only chance of life. At the hour of the consultation the temperature was far from normal, and the pulse had improved. It was, therefore, thought advisable to wait twenty-four hours, in hope that the fall in temperature which had taken place in the last twelve hours indicated a change for the better.

November 5th. Another collapse, with pulse at 140 during the night. Much gas had passed, and the abdomen was less distended. There was considerable vomiting and retching. Temperature 102° , pulse 113. The pain could be more definitely located in about the middle of the pelvis. The same gentlemen were again in consultation, and laparotomy was unanimously agreed upon. Under ether Dr. Fitz thought he felt a resisting mass in the pelvis, but none of the others present were able to confirm this observation.

With Drs. Richardson and Cutler assisting, I opened the abdomen by an incision two and a half inches long, beginning at the anterior superior spine of the ilium, and running parallel to and one inch above Poupart's ligament on the right side. The cecum and the omentum presented. I examined the cecal region and passed my fingers towards the umbilicus, and then down over the pelvis. No cake or fluctuation was felt, but there was a vague feeling that the intestines were more firmly glued together in that direction. On separating these adhesions I opened a foul-smelling abscess, containing two or three ounces of pus, which ran out over the peritoneum. This cavity, when empty, seemed about the size and shape of an egg-shell. It was situated a little to the right of the median line, and just inside the brim of the pelvis. Its walls seemed to be formed by the gluing of intestines and bladder. The vermiform appendix was not seen, as the abscess was nearly three inches from the incision. The abscess and soiled peritoneum being washed with warm carbolized water 1-80, a glass drainage-tube was placed in the cavity, and the wound partially closed. The operation lasted about twenty minutes. There was considerable shock, the temperature rising to 103.2° that night.

November 6th. Temperature 100° , pulse 120. General condition fairly good. Tube discharged freely. Abdomen much distended and very sensitive.

November 7th. Great improvement in every way. Temperature normal, pulse 100.

November 9th. Doing well. A large defecation after taking two S-illitz powders. Tympanites less.

November 10th. Temperature and pulse higher. The patient had severe griping pain. The general distension was much diminished, and a prominence had appeared near the wound. The sutures had been removed, and the wound was sloughy.

November 11th. Under ether, the wound was opened and a quantity of pus, which had collected in the loin, was evacuated. This second abscess was undoubtedly due to contamination of the peritoneum at the operation.

After this the temperature was irregular for a few days, but there was a steady general improvement. The tubes were washed frequently and drained well. Intestinal gas occasionally escaped from the tube.

November 19th. The patient was in excellent condition. Faecal matter was washed out from the sinus.

November 28th. General condition good. No faecal

matter had been observed to come from the wound for several days.

December 5th. The drainage tubes had been removed, and the wound had nearly healed.

Recovery complete.

In the vast majority of cases the perforated appendix gives rise to an abscess, which becomes glued to the abdominal wall, and which can be felt and opened from the outside without opening the peritoneal cavity. In a few cases the perforated appendix is not encapsuled, but remains free in the peritoneal cavity, giving rise to general purulent peritonitis, or it may be the cause of an abscess which forms between the intestines deep in the abdominal cavity, as in the case here reported. These cases present the general symptoms of perforation of the bowel, and are almost always fatal when left without operation. Laparotomy is obviously the operation indicated. Thus far, unfortunately, very few have been saved by operation.

Dr. Weir,² of New York, has recently collected the cases in which laparotomy has been done for perforation of the vermiform appendix. His table includes twelve cases, with three recoveries. With the idea of trying to establish the mortality of this operation, and without discussing the advisability of each operation, I shall include two more cases, one reported by Barlow and Godlee,³ recovered, and one by Gant,⁴ died. This makes fourteen cases, with four recoveries; to which may be added my case, which is almost exactly like Dr. Weir's last case, and we have fifteen cases, with five recoveries.

In these cases the appendix has been removed five times, with only one recovery, Dr. Hall's case. Removal of the appendix, then, increases the mortality. It is, moreover, unnecessary when it is so glued to the intestines as to form part of an abscess cavity which can be drained. When, however, there is general purulent peritonitis, and the perforated appendix is free in the peritoneal cavity, it should be removed.

I am greatly indebted to Dr. Wood, who scarcely left the patient's bedside for two weeks, and who has kindly furnished me with notes.

THE TREATMENT OF INFLAMMATIONS IN THE NEIGHBORHOOD OF THE CECUM.¹

BY E. H. BRADFORD, M.D.

FOUR cases have recently come under my care, which I will briefly mention, arranging them in the order of their severity and using them as types to illustrate the varieties of the affection as met with clinically.

CASE I. Adult, male. Sharp attack of pain in right abdominal region, tenderness and induration over right iliac region, some distension, symptoms disappeared under complete rest and local fomentations.

CASE II. Adult female. A chronic case of some weeks' standing, with a large and increasing mass of induration in the right iliac region, operation advised by Drs. Blake and Fitz. Induration incised and a cavity of some size opened above Poupart's ligament,

¹Read at the meeting of the Surgical Section of the Suffolk District Medical Society, December 7, 1887.

²Med. Record, June 11, 1887.

³Med. Times and Gazette, Dec. 19, 1885.

⁴Med. Record, 1887, XXXI, 22.

a drainage-tube inserted, extending behind and to the outer side of the cœcum. Recovery took place in a few weeks.

CASE III. Adult, male. Sharp attack of right iliac pain, with vomiting and constipation, distention of abdomen, tympanites, collapse, subnormal temperature, slight cyanosis, rigidity of the recti muscles, and later diffused abdominal pain, a suspicion of an induration deep in the right iliac region felt on palpation, under an anæsthetic; operation proposed, but delayed for a short time at the patient's request, afterwards as there was some improvement in the patient's condition, postponed. The patient finally recovered entirely in three months, without any operative intervention.

CASE IV. Female, child ten years old, with dullness, tenderness, pain in right iliac region, fever and some abdominal distention, some constipation, no vomiting. The symptoms became worse, and an exploratory subperitoneal incision was made without detecting the abscess. Patient died twelve days later and at autopsy an appendicitis found with perforation of the cœcum and septic pyelophlebitis of portal vein. The operative wound had healed well and was healthy.

Using these cases to illustrate the usual varieties, a discussion as to treatment, will become a discussion as to treatment of cases of these different kinds.

For convenience, the following propositions are advanced, with, of course, the admission that it is impossible to codify exactly rules of treatment, and that individual judgment must be used in individual cases.

PROPOSITION I. In cases of chronic or subacute perityphlitis without a tumor, or with slight tumor or induration, and without alarming symptoms, an expectant treatment is indicated.

PROV. II. For cases of chronic or subacute perityphlitis with a large and increasing tumor, an extra-peritoneal incision is indicated.

PROV. III. For cases of acute perityphlitis with threatening symptoms and *with* a tumor, an incision is indicated (extra-peritoneal, if possible.)

PROV. IV. For cases of rapidly acute perityphlitis *without* appreciable tumor and with alarming symptoms, an exploratory incision (extra- or intra-peritoneal) is indicated.

Under Class IV. would be included the cases of direct perforation into the general abdominal cavity, more properly grouped under a separate head. There would be little difference of opinion as to the propriety of the treatment suggested in Proposition I, which will include by far the greatest number of cases to be met in private practice.

There would also be a general agreement now in regard to Proposition II, it being understood that the term "extra-peritoneal" is used as a convenient one (not as a strictly anatomical one), indicating draining from behind the peritoneum a subperitoneal abscess or an abscess separated by adhesions from the general peritoneal cavity. Statistics show that the percentage of recovery in such cases is greater after operative interference than after expectant treatment. The same may be said with greater force, with regard to Proposition III.

There is, however, much room for discussion in regard to Proposition IV. On the one hand, it must be admitted that there are a number of cases which recover where there are alarming symptoms, as represented by Case III, in which every symptom pointing to perforation and general peritonitis was present.

The statistics also, of laparotomy in such cases is not very encouraging.

On the other hand it must be regarded as true that the death-rate in cases of this class when left to nature must be very high, and that the conditions being often desperate, heroic measures are demanded. The cases treated by laparotomy are as yet few, and it is fair to reason that with increasing experience the rate of mortality will improve.

The place of incision in cases without appreciable tumor will also be a subject for discussion, whether median, abdominal, lumbar or inguinal. The only general guide we have is the anatomical one as to the seat of the cœcum and appendix. In regard to this matter, Treves's² investigation may be looked upon as of value.

After examining one hundred cadavers, he "found the cœcum usually lying upon the psoas muscle, and so placed that its apex or lowest point is just projecting beyond the inner border of that muscle. In a great number of cases the cœcum is entirely clear of both psoas and iliacus muscles and hangs over the pelvis brim or is lodged within the pelvic cavity. In eighteen cases out of a hundred the cœcum was lying within the pelvis or placed in contact with the upper surface of the bladder or uterus, or wedged in with the sigmoid flexure, or lying actually in contact with the left wall of the pelvic basin. In a majority of cases the appendix will be seen to lie behind the end of the ileum and its mesentery, and to point in the direction of the spleen.

In a certain number of cases, therefore, it may be assumed that the site of the cœcum is irregular and free from the parietal peritoneal surface. An abscess coming, therefore, from the front of the cœcum or the front of the appendix cœci would be isolated, like an island, in a sea of intestine.

These cases, however, would not be the rule, and furthermore, the number would be made smaller by the fact that inflammation of this sort tends to glue the cœcum, even if free, to back wall of the peritoneum, and to curl the appendix backwards.

In many cases, therefore, even of the acute variety and at an early stage, the abscess can be reached without opening the general peritoneal cavity, by the procedure employed in subperitoneal ligature of the common iliac. Although it has been clearly proved at the present time that the introduction of foul pus into the general peritoneal cavity is not necessarily fatal, and may produce no harm, yet it is axiomatic that where it is possible this should be avoided, especially as in a certain number of cases the canal of the appendix has not been occluded by inflammation and by the opening of the abscess into the peritoneal cavity, fæces would be introduced into the cavity.

The subperitoneal exploration of the abdomen has been advocated and carried out by König, Bordenhauer, and lately advocated by the Russians, Sneguiroff and Gulharoff,³ who have shown the feasibility of more extensive exploration than has formerly been used. This was attempted in Case IV, without success, partly through the lack of thoroughness on the part of the operator in attempting a procedure new to him, and partly because the patient was already suffering from septic pyelophlebitis of the liver, and beyond surgical help, but the attempt appeared to demonstrate

²Treves, Jacksonian Prize Essay.

³Centralblatt f. Chirurgie, Nov. 19, 1887. pp. 806.

the slight risk attending a subperitoneal exploration of the sort.

Such a subperitoneal exploration would be unsuccessful from anatomical grounds in a number of cases and laparotomy indicated, but it would seem that this course should be followed where practicable, and be considered in the doubtful cases with alarming symptoms where, owing to abdominal distension, palpation gives but little indication of condition of the back wall of the peritoneum.

Lawson Tait has said that he would open the abdominal cavity as readily as he would "put his hand in his pocket." We all of us naturally desire to emulate the success of the great English surgeon, but it should also be remembered that Verneuil is not far from wrong in saying that the present age is seized with a rage for bold surgery, a "*mania secandi*" a "*déire opératoire*," and that it is true that the best surgery is that which wins success while exposing the patient to the least possible risk.

REPORT OF PROGRESS IN GYNECOLOGY.

BY F. H. DAVENPORT, M.D.
Assistant in Gynecology, Harvard Medical School.

PATHOLOGICAL ANATOMY OF MEMBRANOUS DYSMENORRHEA.

DR. H. MEYER,¹ in an article on this subject, considers as true dysmenorrhœal membranes only those which, on microscopical examination, prove to be thrown off uterine mucous membrane. Our knowledge of the pathological anatomy of this disease is still very imperfect. The author describes eleven cases which he examined, and gives the microscopical appearances as follows: Smooth surface, a few lengthened gland tubules, enlarged and filled bloodvessels, great hypertrophy of the cell elements, with structures which resemble decidua and giant cells. In all the preparations one could see the endeavor towards cell growth, at the expense of the gland tissue.

In two cases in which the author scraped the mucous membrane three days before the menstrual period, he found endometritis, once of an exquisite glandular type, and the other more interstitial. The membranous dysmenorrhœa is, therefore, not associated with any one disease of the uterine mucous membrane. The important factors in the production of the pathological membrane seem to be marked injection and dilatation of the vessels, and increase in the cell elements of the intermediate tissue, by which the glands are pressed upon and narrowed. The author considers it probable that a suddenly occurring state of erection of the mucous membrane contributes to its separation, and the contractions of the uterus effect its expulsion.

PLASTIC OPERATIONS ON THE PERINEUM.

Dr. J. Veit² gives in this article his personal views of operations on the perineum. Starting from the universally accepted necessity of an operation in cases of complete rupture and marked prolapse, he next considers the question of the choice of method of operation, and recognizes any method as satisfactory which, with a moderate narrowing of the vagina and vaginal insertion, really forms a perineal triangle.

Healing by first intention depends entirely upon thorough antiseptics, and alone gives prospect of success. In addition to perfect cleanliness of instruments, operator, and field of operation, the author lays great weight on more or less frequent irrigation with a weak solution of sublimate ($\frac{1}{2}$ -1:5000). He considers it unnecessary to spend time over smoothing the refreshed surface, and while recognizing that good results have been obtained with various forms of suture, he considers that the continuous suture with catgut has the advantage, on account of its easy and quick application. The catgut which he recommends is that preserved in oil of juniper. The shape of the part to be refreshed should be as simple as possible, and he has had the best results with Sims's or Simon's in cases of complete rupture, and Bischoff's in incomplete, though other methods have given him good results. Fistulae have become more rare, and are to be considered the result of faulty antiseptics. The total extirpation of the uterus for procidentia is unwarrantable. So, too, the amputation of the cervix to reduce the size of the uterus is very rarely necessary, inasmuch as the hypertrophy will often disappear when the prolapse has been cured by operation.

NINETY CASES OF "ONE CHILD" STERILITY.

Attention has been lately drawn to this subject, and Professor Kleinwächter³ studied ninety cases of this relatively frequent form of sterility with reference to the cause. The cases, the details of some of which are given, are all of women who had either had one child at full term, or aborted once. Kleinwächter attempts to classify these in groups, according to their causes, but recognizes sources of error from the fact that often several diseases were present in the same case, any one of which would be a sufficient cause for the sterility.

Group I embraces the cases of inflammatory processes of the genital organs, the results of puerperal diseases, exudations after peri- and parametritis, oöphoritis, fixation of the uterus, with or without displacement, chronic metritis, sixteen cases. II, inflammatory processes and their results, not connected with the puerperium, eleven cases. III, chronic catarrh of the cervix, fifteen cases. IV, dislocation of the uterus, eleven cases. V, new growth of the uterus, eight cases; one mucous polyp and seven fibromyomata. VI, atrophy of the uterus, five cases. VII, new growths of the ovaries, three cases. VIII, causes outside the genital organs, seven cases: malaria and latent gonorrhœa, heart disease, gall-stones, one case of alcoholism, two cases of well-defined chlorosis, obesity. Group IX includes six cases for which no cause of the one child sterility could be found. Group X comprises seven cases of impotence of the husband. There were also, in addition to the chief complaints, in all the cases numerous complications.

Since in nearly half the cases there were inflammatory processes, partly a direct result of the first pregnancy and partly independent of it, the author looks upon this as a well-defined cause of the sterility. The causes operative in groups V - VII, except the case of the mucous polyp, he also considers sufficient. So, too, with group X, and probably in group VIII in the cases of chlorosis, with anomalies of menstruation, heart disease, and alcoholism. In the

¹ Arch. f. Gynäkol., XXXI, 1, 1887.

² Deutsche Med. Woch., XIII, 38, 1887.

³ Zeitsch. für Heilkunde, VIII, 4, 1887.

other groups the condition of the genital organs is no sure cause of the sterility. This applies to cases of uncomplicated malpositions of the uterus, and of catarrh of the cervix, though Kleinwächter does not deny that the latter may be a cause in certain cases.

The author considers the prognosis in many of the cases as favorable, provided appropriate treatment were instituted. He recognizes the importance in doubtful cases of examining the sperma of the husbands.

A YEAR'S WORK IN LAPAROTOMY.

Dr. P. F. Mundé⁴ gives the account of his experience in abdominal surgery from October, 1886, to January 1, 1888, twelve working months, during which time he performed forty-five laparotomies. Of these, twenty-two were ovariectomies, thirteen salpingo-oophorectomies, two oophorectomies, two hysterectomies, four exploratory incisions, one for encapsulated intra-peritoneal abscess, and one for intestinal obstruction. There were eight deaths: five of the first category, one of the second, and of the last two. Mundé includes under the head ovariectomy, tumors of the ovary, great or small, and cysts of the broad ligament; under the second head the removal of diseased tubes, chiefly the operation commonly called Tait's; under oophorectomy, the removal of ovaries and tubes which macroscopically do not appear diseased, with the object of bringing on the menopause.

Among the especially interesting cases were three complicated with pregnancy. The first one was a large ovarian cyst in a woman who was five months pregnant. There was constant vomiting for three days after the operation, which was controlled by dilating the cervical canal thoroughly with the index finger, and a hypodermic of morphine over the epigastrium. The pregnancy went on to full term.

The second case was a large multicellular dermoid tumor, complicated with pregnancy. Premature delivery was induced at the seventh month, the result being a living child, and the tumor was extirpated five weeks afterwards with success.

The third case was of a dermoid cyst of each ovary, with pregnancy at five months. Difficult operation owing to old chronic peritonitis, from rupture of one cyst a year and a half before. Premature delivery on the third day. An interesting fact was that one of the tumors contained black, the other blonde hair.

One case was particularly interesting, as it was the third laparotomy for abdominal cyst in the same patient. In March, 1881, an intra-ligamentous ovarian cyst of the left side had been removed in Berlin, and in December of the same year a similar one of the right side. In May, 1887, she consulted Dr. Mundé for a large ventral hernia. An abdominal cyst was detected, which proved to be situated between the layers of the broad ligament of the left side. Patient was cured both of her cyst and of her ventral hernia.

One of the oophorectomies was performed for hysterio-epileptiform seizures, which the patient had had since the beginning of menstruation. All resources seemed to have been exhausted, and the ovaries were removed. There was marked improvement for several months, but ten months after the operation her condition was very much the same as before the operation.

⁴ Am. Jour. of Obs., January, 1887.

The only laparotomy for intestinal obstruction was in the patient who heads the list, upon whom Dr. Mundé did ovariectomy during pregnancy. Symptoms of obstruction came on two days after delivery, but consent to the operation was delayed a number of days. Then constriction was found from firm bands of adhesions. The patient lived only a few hours.

The details of a number of other interesting cases are given, for which the reader is referred to the article.

ON THE FREQUENCY OF MALE STERILITY.

According to F. A. Kehrer⁵ the cause of the sterility in many marriages is to be sought for on the side of the husbands oftener than has been supposed. This is apparent from the examination of the sperma, which Kehrer has made in ninety-six cases. In three per cent. there was impotentia coeundi, in all of which cases masturbation had been an element. The men suffered either from frequent pollutions, or from a premature ejaculation before there was complete immisio penis. In these cases conception may follow if a cylindrical speculum is inserted into the vagina before coition is attempted. In several cases this was tried with success.

In thirty per cent. there was azoöpermia, and in these cases there was generally a previous history of gonorrhoea, with single or double orchitis. The author lays especial weight on the occlusion of the ductus ejaculatorii from gonorrhoeal prostatitis. He also found azoöpermia in cases where there had been no previous disease and there was nothing abnormal about the genital organs.

Oligozoöpermie existed in eleven per cent., with a previous history of gonorrhoea with orchitis, or syphilis, and usually masturbation. The author concludes that the diseases of the female genital organs, which are a cause of sterility, are very much fewer than is generally supposed. The most common cause he considers to be catarrhal affections, and he believes that there are bacteria present in these cases which destroy the ovum. It is a question whether the bacteria excite the inflammation in the mucous membrane, or whether they find in it favorable conditions for their development.

DIAGNOSIS AND SEPARATION OF PERITONEAL ADHESIONS OF THE RETROFLEXED UTERUS AND DISPLACED OVARIES.

Dr. B. S. Schultze,⁶ referring to the difficulty of treating the uterus when bound down in a retroflexed position by adhesions, the result of peritonitis, gives the details of a method which he has practised himself with marked success. These adhesions are often lax, or may be stretched by a reposer so as to bring the uterus into a normal position, but the malposition returns sooner or later. So, too, massage will often accomplish much, and a suitable support will now and then relieve symptoms, even when the uterus is not in a thoroughly good position. Schultze's method, which he has described before, has been only very exceptionally practised, and most writers express themselves with a good deal of reserve as to its practicability and safety.

The patient, having been anesthetized, is placed upon the back, with the thighs flexed and abducted.

⁵ Beit. zur klin. und experiment. Gyn. und Gyn., II.

⁶ Zeit. für Geb. und Gyn. XIV., Band. 1 Heft, 1887.

The fore and middle fingers of the left hand are introduced into the rectum, and faecal masses removed by irrigation. In order to easily pass the fingers above the isthmus of the rectum which lies in the neighborhood of the folds of Douglas's pouch, the irrigation is best continued. The right hand makes firm pressure over the abdomen. The body of the uterus is gently raised with the fingers in the rectum, and its contour, as well as that of the tubes and ovaries, carefully palpated. Sometimes the adhesions can be immediately made out. The fundus is carried as far forward as possible, and held forward by the right hand, and the character, point of origin and course of the adhesions carefully noted. Broad adhesions are separated with the finger-tips, much as an adherent placenta is separated from the uterine wall. During this manoeuvre the assistance of the right hand is necessary to fix the uterus. Separate bands are seized by the fingers in the rectum and separated from the peritoneal surface of the uterus by pressure with the hand through the abdominal wall, as close as possible to the uterus.

If the uterus is adherent over a broad surface to the anterior wall of the rectum it is separated by working the uterus forward with both fore-fingers, while the middle fingers steady the free surface of the rectum above the adhesions.

Similar manipulations are to be carried out in the cases of displaced ovaries, care being taken not to make pressure on the ovaries themselves, but on the adherent surfaces.

Schultze has never seen any severe peritonitis or inflammatory thickening, or hamatocele follow. He recommends the method only to those operators whose sense of touch is very acute. The uterus needs usually to be held in position by a pessary for a time after the operation.

Clinical Memoranda.

A CASE OF STRICTURE OF THE RECTUM TREATED BY INCISION.¹

BY EDWARD ECKFOLDS, M.D.

Mrs. B., twenty-nine years old, and a native of Halifax, presented herself for examination in the rectal room of the Boston Dispensary on June 8, 1887, with the following history:

Was in good health until she was twenty-two years old, when her second pregnancy terminated spontaneously in a rapid labor at seven months, but was followed by an illness, which she calls "inflammatory fever," of six weeks' duration, during which she had great abdominal pain and tenderness, was extremely constipated, and experienced more or less pain whenever her bowels moved.

Since then she has never been free from pain at stool, which was, however, endurable until two years ago, when it began to be severe, to persist for an increasing length of time after defecation, and to be accompanied by blood.

These symptoms steadily increased, till, at the time when she was first seen, she suffered from more or less constant pain, and was subject many times a day to attacks of intense tenesmus, during which she felt obliged to make violent and extremely painful strain-

ing efforts, during which a fleshy mass nearly two inches in length frequently protruded from the anus. The stools had steadily decreased in amount, and at this time frequently consisted of nothing but a little bloody mucus. She had no appetite, and frequently for days together was excited to nausea by any attempt to eat. Her cachectic appearance strongly suggested the latter stages of malignant disease, and she was, for the most part, confined to the house by pain and weakness, and by her liability to attacks of tenesmus.

On rectal examination, the anus were retracted and the sphincter tightly closed, and, on inserting the finger, it was arrested about half an inch above the sphincter by a firm and rigid stricture, with irregular and ulcerated edges, but of uniform shape and consistency. Its orifice was sharp-edged, and of about the size of an ordinary pen-holder, not admitting even the tip of the finger.

On the insertion of a speculum, the stricture was plainly visible, foul, bloody muco-pus oozing freely from its orifice.

No specific history could be obtained, and no secondary deposits could be found in the pelvis.

For three weeks, the stricture was dilated with the forefinger on every third day, in spite of the great pain which attended and followed each attempt. At the end of this time the lower edge admitted the finger as far as the base of the nail, but the upper part was still firmly resistant. She then had an attack of pelvic pain, which kept her in bed for a week, and on her reappearance at the end of this time, the stricture was found to have returned to its original condition.

It was easily re-dilated to the former extent, but as little or nothing more was gained during the next two weeks, as she was distinctly failing in strength, and was evidently in a condition in which she could not last long without relief, she was recommended to have the stricture cut; and, on July 19th, she was etherized at her home, and, with the kind assistance of Drs. R. W. Lovett and G. C. Munro, I dilated the sphincter and divided the stricture by a free incision, with a probe-pointed bistoury, in the median line posteriorly, cutting through into the peri-rectal tissue, and extending the incision up and down, till no constricting bands could be felt, but leaving the external sphincter untouched by the knife.

Little or no hamorrhage occurred, but as she lived at some distance, the rectum was packed with iodoform tampons, after being thoroughly washed out with a weak solution of carbolic acid, and a drainage-tube was placed among the tampons to permit the passage of flatus or liquid feces.

During the night there was slight tenesmus, easily controlled by morphia; in the morning the temperature was 101.2°, and a slight, but very foul discharge was escaping from the anus. The packing was removed, and the rectum again washed out. The temperature was normal in the evening, and was never above 99° again.

Twenty-four hours after the operation, the patient volunteered the statement that she was more free from pain than for years before. On the second day she had a good, spontaneous movement of the bowels, followed by moderate pain. By the fourth day she was eating well, and from that time on had a daily movement, without any great pain, and under the influence of a very moderate cathartic.

I had intended to have kept her in bed until the

¹Read at a meeting of the Surgical Section of the Suffolk District Medical Society, December 7, 1887.

wound had healed, but she got up on the third day, and remained up in defiance of orders, though without any immediate ill result.

A full-sized bougie was passed with ease on the fifth day, and has been passed at short intervals ever since.

At the end of five weeks the patient had gained eleven pounds, was blessed with a large appetite, and from an appearance of advanced cachexia, had become a very fairly healthy-looking woman. The stricture was re-established at its old site, but was short, soft, and elastic, in marked contrast to its condition before operation.

Since then there has been some gain in general condition, with but very little change locally. The bougie is now passed once a week, and its passage is still painful. There are still considerable ulcerations about the stricture, which yields very slowly to treatment, and the amount of pain caused by the bougie appears to vary with the size and condition of the ulcers, but the pain at stool is but slight. The patient has gained very greatly in flesh and strength, and is now able, on the whole, to enjoy life, though she will probably never be able to discontinue the use of a bougie.

CAUSATION.

No trace of a venereal history could be obtained from either the patient or her husband, except that he had had a "sore" seven years before marriage, which healed in ten days under the use of castile soap and a dressing of hard.

The stricture was sharp-edged, and uniform in shape and consistency, and all trace of induration disappeared so completely on its division, that for some weeks it was difficult to recognize its site.

In view of these facts, it seems to me that syphilis and malignant disease are unlikely causes, and that this case is probably one of those in which stricture results from simple ulceration. The symptoms all date from a period when the tissues were depressed in vitality by a puerperal illness of probably septic origin; and the authority of almost all writers on rectal disease leads to the belief that such a condition may give rise to rectal ulcerations of a low type, and that the existence of these simple ulcers, if prolonged by neglect and constipation, may be an efficient cause of cicatricial stricture.

CASE OF PERITYPHLITIC ABSCESS, BURSTING INTO THE INTESTINES.—RECOVERY.

BY O. W. DOG, M.D.

Mrs. B., aged 30. Very constipated for the last three years. Before that time, bowels unnaturally loose. On October 30th last, having had no movement for three days, she strained very hard at stool, but felt no immediate ill consequences. The following day, after exposure to cold, she had quite a severe chill, and later in the day (after dinner) another slight one, followed by fever and intense pain at the epigastrium. She vomited late in the evening, but the pain was undiminished until the following morning, when she took morphine subcutaneously, and was obliged to have this repeated in the afternoon. Two days later she felt a soreness just below the level of the umbilicus, and an inch and a half to the right of the median line. Though this continued she went to drive on the

following days (Friday and Saturday). The bowels were natural. On Monday, while adjusting her corsets, she experienced a very severe pain at the sensitive point referred to. Notwithstanding, she went to the dressmaker's, fainting three times while there, but persisted in taking a drive in the afternoon. The following morning (Tuesday) she suffered intense pain in the ileo-cæcal region, the pain radiating both upwards and downwards. This pain continued until the Thursday night following, when it suddenly ceased, and she felt something give way at the tender point. On Friday she had a severe chill, followed by fever, free perspiration, and wakefulness. The chill was repeated on Saturday, but was not so severe as the previous one. On Sunday she had frequent dejections; none on Monday, but four on Tuesday; and on the evening of that day I saw her for the first time. She was very pale, face pinched and sallow, and was lying on her back, being unable to lie on the left side on account of a dragging it produced in the cæcal region. In this region the abdomen was more prominent than elsewhere, and palpation showed a hard mass, about three inches in diameter, tender on pressure, and giving, on manipulation, a gurgling sound. Light percussion gave a tympanitic note, heavy percussion marked dullness. There was no fluctuation at any time. A discharge from the bowels soon after my examination was very thin, light-clay colored, and contained a large amount of pus. Temperature 104.2°, pulse 124. Dr. Porter saw her with me in consultation, and advised stimulating and supporting treatment. The following morning at nine, temperature 103°, pulse 116. Tumor more marked than last night more dull. No defecation since last evening. 5 p.m., temperature 103.9°, pulse 118. 10 p.m., temperature 104.2°, pulse 122. During the day she had had one large offensive purulent defecation. Constant nausea, but no vomiting. Next morning, November 17th, temperature 103°, pulse 100. 7 A.M., one defecation through the night of same character as the others. The tumor seemed more diffused than when she was first seen. 2 p.m., temperature 103.8°, pulse 120. Three defecations since morning, one purulent, the others dark-chocolate color. At 8.30 p.m., temperature 102.5°, pulse 120. Five more defecations, dark in color, and containing some pus. Quinine and digitalis prescribed. A consultation with Dr. Porter and Dr. John Homans was held next morning at 10, when temperature 100.6°, pulse 100. Four defecations during the night. Had slept well. General appearance much improved. No operation was deemed advisable unless the intestinal opening should again become closed, as it had two days previously, and there should be a marked rise of pulse and temperature, as evidently now the abscess was draining freely into the intestines. From that time until now (December 7th), there has been steady improvement in her general condition, so that now she is sitting up daily, has a good appetite, and bowels are moved daily, though by enemata. The defecations are formed and natural in appearance. The tumor has apparently wholly disappeared, as no induration or dullness has been detected in the last three days. The pulse and temperature became normal on November 21st.

—Some of the mind curers append to their names, "M.D.," which being interpreted, means Mind Doctor.

Reports of Societies.

SUFFOLK DISTRICT MEDICAL SOCIETY. SURGICAL SECTION.

G. H. MONKS, M.D., SECRETARY.

MEETING of Wednesday evening, December 7, 1887, the Chairman, DR. J. COLLINS WARREN, presiding.

DR. EDWARD REYNOLDS reported a

CASE OF STRICTURE OF THE RECTUM TREATED BY INCISION.¹

DR. WILLIAM D. HODGES said: I am very glad to hear Dr. Reynolds's account of the operation he has performed, and its successful result, and to be able to supplement his paper by a short account of one which I performed in October for a syphilitic stricture. I performed rectotomy, making my incision posteriorly, and cutting into the tissue between the coccyx and rectum: and although it gave considerable relief, the patient, at my direction, still uses a No. 7 bougie, to keep the stricture from contracting again. The stricture was not very resisting at the time of the operation. On introducing the finger, you came to a very decided ring, with a dilatation above. I am doubtful whether this patient might not have been successfully treated by the use of bougies alone. My experience with other strictures of the rectum which I have seen, demonstrates to my mind the fact that incision is not always a successful operation. I have seen some three or four cases of stricture, two of them malignant, the others of an inflammatory character; that is, I call them inflammatory, but the present authorities rather discountenance the fact that any stricture can exist as a purely inflammatory affair: most of them being due to venereal disease, and not to pelvic cellulitis or anything of that kind.

One case of malignant stricture is interesting from the subsequent history, and the length of time which I have had it under my observation. The patient, a woman, appeared at the Boston Dispensary some two years ago, with what proved, on examination, to be a stricture, which was passable by a No. 5 bougie of Tiemann's make. It was dilated, and she went away in June, being able to pass a No. 8. When she returned in the autumn, it was impossible to pass a No. 3. The stricture was slowly dilated, but the disease had involved so many tissues, including the uterus, that it could be felt as a large mass in the vagina. During the winter she went along fairly well, with occasional attacks of cellulitis; or, rather, she had attacks when she could not have a movement of the bowels, and was in great pain, with the temperature at 103° and 104°. At these times, I found the use of morphia, besides dulling pain, had some effect upon the stricture. After taking two or three doses of an eighth of a grain of morphia, the bowels would be relieved. I find that this has been the observation of Dr. Kelsey, who has recently reported a case which terminated fatally, where he found that the use of morphia was of great assistance, not only dulling the pain, but creating a movement of the bowels. My patient is to-day under observation, but the stricture is impassable by any rectal bougie, although it is passable with a catheter. She is unwilling to have colotomy performed, or to go to any hospital. She is un-

able to bear food, and the nourishment she takes is very slight. She is slowly dying from inanition.

Another of my cases of stricture was interesting from the number of complications and injuries from which the woman suffered. She appeared two years ago at the Dispensary for stricture. On examination, I found this condition of affairs: a stricture that was passable by a No. 5 bougie. In addition to this, a partial rupture of the perineum, a recto-vaginal fistula, a rectocele, and a double inguinal hernia. She had had syphilis. She had no great difficulty with defecation, her chief trouble being with the rectocele, which appeared at the vaginal orifice as a tumor of about the size of a cocoon, and had to be pushed back every time she wished to have an operation.

The great trouble with dilatation is that it is extremely painful, and the pain seems to be out of proportion to the extent of the disease. Dilatation is the more conservative way of treating the disease, for if you perform rectotomy in annular strictures, the cicatrix which results may prove an evil, rather than a benefit. The amount of contraction that an incision creates is considerable. If you make an incision into the diseased tissue, you get a gaping surface, to be filled with granulations, which, in healing it, draw the whole thing together, so that you get a certain puckering at the point after it has cicatrized, which is rather detrimental than otherwise. I think that with the use of bougies you can keep the contraction properly dilated, and allow a sufficiently free passage of feces, as well as by the use of the knife.

DR. E. H. BRADFORD and DR. M. H. RICHARDSON then read papers on the

TREATMENT OF INFLAMMATIONS IN THE REGION OF THE CÆCUM.²

and DR. J. W. ELLIOT reported a

CASE OF PERFORATION OF THE VERMIFORM APPEN- DIX, CAUSING AN INTRA-PERITONEAL ABSCESS AND GENERAL ADHESIVE PERITONITIS.³

For the discussion which followed the reading of these three papers, the following propositions were formulated:

(1) For cases of chronic or subacute perityphlitis with a small tumor, or without tumor, expectant treatment.

(2) For cases of chronic or subacute perityphlitis with a large and increasing tumor, extra-peritoneal incision.

(3) For cases of acute perityphlitis with threatening symptoms and with tumor, extra-peritoneal incision.

(4) For cases of rapidly acute perityphlitis with alarming symptoms, and without appreciable tumor, exploratory incision (extra- or intra-peritoneal).

After reporting his case, DR. ELLIOT said: I wish to say a word about laparotomy in the "fourth class" of cases, as I think it has not been given its proper place by the preceding readers.

I shall speak only of the acute cases with alarming symptoms, and without appreciable tumor. In such cases the diagnosis will be more or less uncertain. The patient will always be in poor condition. These are critical cases. If you do anything, you must do the right thing, and do it quickly. Dr. Bradford advocates the extra-peritoneal exploration for these

¹ See page 92 and page 88 of the Journal.

² See page 92 of this number of the Journal.

³ See page 97 of this number of the Journal.

doubtful cases. It seems to me that these are just the cases for exploratory laparotomy. I am disposed to regard the extra-peritoneal exploration as a theoretical operation, easily done in the dissecting-room, but of no practical value in this class of cases. Neither of the gentlemen who have advocated this operation have referred to a single case where it was successful. I have never seen such a case reported. On the contrary, Dr. Bradford has just reported a case where it was not successful. Dr. Harrington will record a case where it was not successful, although he was able to feel a tumor by rectum.

In some of Dr. Richardson's experiments on the cadaver with this operation, he found that the appendix was only two inches from the incision. In my case just reported (where there was considerable distension), my incision was an inch higher than his, yet it was three inches on a straight line to the abscess. If I had gone behind the peritoneum I should have been four or five inches away, and probably could not have reached it without opening the peritoneal cavity.

If the case turns out to be, not a case of appendicitis, but some form of intestinal obstruction, the extra-peritoneal operation is worse than useless. In several of the cases referred to in my paper, there was a general purulent peritonitis, with a perforated appendix lying free in the abdominal cavity, which required excision. In such a case a laparotomy, of course, is indicated, but a previous extra-peritoneal exploration might so exhaust the patient that a subsequent laparotomy would be impossible, as in Dr. Harrington's case. This extra-peritoneal operation, then, seems to me a most excellent one where there is a tumor, because it can in this way be opened without involving the peritoneal cavity; but in these blind cases which come in the "fourth class" it is too uncertain.

Exploratory laparotomy, on the other hand, is the surest way to find the trouble, and the most intelligent way to treat it. The chief objection, to laparotomy is that it occasionally involves unnecessary contamination of the peritoneum with foul pus. Now, if by exploratory laparotomy an abscess is found which could best be drained extra-peritoneally, this can still be done, and has been done under such circumstances. If the abscess is so situated that it cannot be drained without contaminating the peritoneum, then laparotomy is necessary. I think, also, that the danger from contaminating the peritoneum with pus has been greatly exaggerated. I have, myself, unavoidably or accidentally contaminated the peritoneum with fetid pus in four cases, and all have recovered as rapidly as the average of severe abdominal cases. The journals of the day are full of such cases. The high mortality of laparotomy for appendicitis seems to me to be due not so much to contamination of the peritoneum with pus as to the difficulty of making a diagnosis, and the consequent delay in operating.

Dr. CREEVER: I am sorry that I cannot add anything to the operative part of the subject, but I will allude to a few cases that happened in my own experience, without operation. Until quite recently, operations were not thought of; but I happen to have seen cases of all these classes, which well illustrate their relative mortality.

In the first class; namely, cases of chronic or subacute perityphlitis, with a small tumor, or without tumor, treated expectantly, I recall very distinctly two cases, one of which happened only a little while

ago. I was particularly struck by the remark that one of the gentlemen made about the symptoms in one case being like those of renal colic. I was called to a gentleman who was suffering from what I supposed to be an attack of renal colic. The pain was in the right side, directly behind the cecum, and extended into the groin and testicle. The patient had waked up in the night with vomiting and intense suffering. He was put under the influence of morphia. The next day there was improvement, and, as soon as the first symptoms of renal colic passed off, then there began to be present pain directly in front, which continued six days over the region of the cecum.

On the fourth day, I was quite positive that I felt a lump. The mildness of the symptoms, particularly the fact that the temperature and pulse were little raised, induced me to wait, and on the eighth day the patient had resolution, with action of the bowels, and recovery. I am inclined to think that this was a case of cellulitis behind the cecum, which was absorbed.

I saw, out of town, a year or two ago, a patient who had had five or six of these attacks. He had them every few months. He had a marked tuberculous history. It seemed probable that whatever trouble there was, was of a tubercular nature. It was also limited to one spot, and never passed on to a general peritonitis. Each attack lasted a week or more, and each resolved. Nothing was done. These cases belong to the first class.

In the second class, cases of chronic or subacute perityphlitis, with an increasing tumor going on very slowly, I had a case which I reported some time ago, where a large abscess was opened, and proved to be extra-peritoneal.

Of the third class of cases, with threatening symptoms and a tumor, I have had three cases with recovery. It is understood, of course, that in no one of these cases was an operation thought of. They happened a good many years ago. They all recovered after six or eight days by quieting treatment with opium.

Now we come to the last class of cases, which are the more terrible ones, cases of rapidly acute perityphlitis, without apparent tumor, and with alarming symptoms, threatening, or absolutely becoming true peritonitis. I have four cases, of which all were fatal. The history of all of them was quite exact. One was a lady who was seized suddenly in church with intense pain about the cecum, and developed, gradually, all the symptoms of general peritonitis. After various treatment by medical means — no surgery being thought of in those days — she died on the fifth day.

The next case was a young man (and I recollect all these cases very distinctly, because they were so sad to go through with at the time) — a young man who was seized with sudden colic. He went out and took a dose of salts, and then walked about for some time in the wet streets. He came to me with an undoubted lump in the right iliac fossa. That developed speedily into general peritonitis, and he died within the first week. Another case was almost similar, and the last had almost identical symptoms. All of these cases were fatal in less than a week, and all with symptoms of general peritonitis. They all apparently had a local origin, and I little doubt now that they were due to perforation, followed by general peritonitis. I can recount nine cases, of which five were fatal, and four recovered. All the severe ones died.

I think one of the earliest extra-peritoneal operations done here was by Dr. Thorndike, eight or nine years ago. At the time, it attracted considerable notice, because the operation had not been done very often. In this case the abscess was found by an incision, as if to reach the iliac artery. The patient recovered.

So far as I am enabled to express an opinion, my experience would show that nothing is more hopeless than peritonitis when it is once fairly under way, and almost any operation is justifiable which promises to afford relief; and there is nothing to do, perhaps, but laparotomy. The only point is whether the next ten years is going to show an increasing percentage of recoveries after laparotomy. So far it is very small; and we may, perhaps, infer that it is so because the operation is still new, and that we have not enough experience.

I suppose the great trouble here will always be in establishing the diagnosis—just as in cases of internal strangulation—as to whether it be due to any remediable cause, and whether it be justifiable to make an incision. There is the difficulty of diagnosis, and a reasonable hesitation about making an operation, unless you are pretty clear, because the percentage of recoveries is so small.

In regard to the extra-peritoneal operation, I think, in the class of cases to which it is adapted, there should be no hesitation whatever. If no abscess is reached, the incision does not subject the patient to much more peril. If it is done antiseptically, it is not likely to light up any pelvic cellulitis or abscess, unless it were already present before the incision were made.

I suppose that this part of the subject would hardly embrace that form of peritonitis which is called tubercular, chronic peritonitis with effusion, and the benefit of operation in such cases. If any gentleman has cases which can throw light upon it, I would be glad to hear what the result is in such cases.

DR. JOHN HOMANS: There is a great deal I would like to say. In the first place, I would like to ask Dr. Elliot if, in doing the operation, he put in a drainage-tube after opening the abscess.

DR. ELLIOT: I did put in a long, glass drainage-tube.

DR. HOMANS: About twenty-five years ago, I remember making an autopsy in South Boston on a boy between ten and twelve years old, where a diagnosis of typhlo-enteritis had been made, and an abscess was found at the autopsy. The next case was one of Dr. Francis's in Brookline, an adult female. I made that autopsy: it was the same thing, and a foreign body was found. The diagnosis was correctly made, and then they waited for the autopsy.

I made up my mind that I would not wait for the autopsy if I ever had a case. In these cases the diagnosis was always made, and we always found the pus. The next case was a cousin of mine, who had been eating a good many raisins. He died within a week, and we found the raisin-seeds. The first time that laparotomy was done in this city for perityphlitic inflammation was two years ago. The boy was ten years old. I saw him upon the fourth day after he had had any symptoms, and I made up my mind that this boy would go through the same course as the others, and that we could find out what was the matter before he died. I knew that incision of the

peritoneum was harmless, and that if I could find an abscess, perhaps his life could be saved.

The point is to make the opening, and not to talk too much about where to make it. You discuss all these anatomical points, and in the meantime the patient dies. It reminds one of a case of hæmorrhage from a vessel in the neck. A consultation was held to decide what vessel it was. It was finally decided to be the inferior thyroid. In the meantime, the man died. The point is to interfere. This boy had no tumor that I could feel; his abdomen was distended, and there was tenderness and a feeling of resistance in the right side. I made my incision two inches above, and a little to the outside of the right anterior spine of the ilium. I came down upon healthy intestines, and I thought I had made a mistake, but, on separating these intestines, I found that the coils below were stuck together. Separating these, offensive pus, with the odor of rotten eggs, came out. The pus must have flowed in among the intestines after I opened the abscess. I put in a double drainage-tube. The boy got well, and is now well and strong, without a hernia. The tube was kept in about a fortnight. The case was reported in the JOURNAL in the early part of 1886. It took me fifteen years of ovariectomy, and twenty years of experience to know enough to do this, and to have the confidence to try it.

Of course, you don't want the pus to get into the abdominal cavity, yet Dr. Elliot will remember helping me once when the contents of the bowel must have gotten in, but it did no harm. This boy had no trouble. If I had aspirated at the point of resistance, I should have penetrated the bowel four times. If I had gone in just below the right kidney, and pushed forward through the mass of muscles, and you know how very deep it is, I should have struck the pus if I had gone far enough. That was the only other place where it seemed to me of use to make an incision. Perhaps, if I had gone in where we tie the iliac artery, I might have opened the abscess.

It seems to me that the practical point in these cases of typhlo-enteritis is to open the abscess either through the peritoneum in front by laparotomy, or lower down. I don't see how an abscess of this kind can be anything but intra-peritoneal, unless it has found its way to the surface.

DR. G. W. GAY: I have had quite a number of the first three classes of cases. I have had but one of the fourth class, in which I have seen an autopsy. This was nearly twenty years ago; the boy had characteristic symptoms of trouble with the appendix, and died within six days. At the autopsy, there were found concretions in the appendix, which was ruptured, though there was no pus in the peritoneal cavity. There was extensive general peritonitis of a very marked degree. I have often thought, since laparotomy has come up, what good would laparotomy have done in this case. There was certainly nothing to gain. The few cases of general peritonitis seen by me in which laparotomy has been done have all died.

Of course, one of the fundamental principles of surgery is to give exit to pus; but if you have a general peritonitis without pus or serum, I fail to see the good of doing an operation. In a case like Dr. Richardson's, where the symptoms were not localized at all, it seems to me it is somewhat hap-hazard surgery to operate. I don't see why you may not operate on any case of idiopathic peritonitis with just as much reason as upon

that one. A person is seized with general peritonitis, without localization of symptoms. Dr. Richardson's case proved to have been an abscess, and, of course, the operation was justifiable.

There is another side to this story of inflammation of the appendix. I have seen one case within a month, and two others have come to my knowledge within the past year, where a patient has gotten well from undoubted inflammation and perforation of the appendix. In two cases, the perforation was followed by fecal fistula. One of the cases was in my office within a month. He now has a fistula which opens once in a while and discharges a little. The symptoms were characteristic, and there is no doubt of the diagnosis at all. He was seized with pain, went to bed, and had alarming prostration in forty-eight hours. These are the cases that require prompt operation, and come in the fourth class. I have known three cases that have gotten well without operation. I do not mean to say that they would not have gotten well better and quicker with the operation than without. But they do not all die. The extra-peritoneal cases should, of course, be treated like abscesses anywhere else. You make an incision, and if you don't find pus you have done little or no harm. But when you go into the peritoneal cavity, that is a different thing. As I said before, I have never seen a case of acute peritonitis recover after laparotomy, and hence I think these cases require care, and that the peritoneal cavity is not to be opened upon slight grounds, or without due consideration and pretty marked symptoms.

Dr. Fitz: I should like to emphasize still more strongly, if possible, the point made by Dr. Homans, that the majority of these cases at the outset are of circumscribed peritonitis. As a rule the abscesses are not behind the cecum or in the iliac fascia, but are within the peritoneal cavity, and are included between peritoneal adhesions.

The diagnosis in general presents but little difficulty, especially in the male. In the severest cases the question is essentially one of acute intestinal obstruction from causes originating in the lower right abdominal quadrant, or of perforating appendicitis. It is far preferable to risk the evacuation of pus during life than to establish the diagnosis, as has so often been the case, at the autopsy.

The use of the terms extra- and intra-peritoneal incision for the necessary operation seems likely to obscure the nature and seat of the disturbance and the operation for its relief. Since the pus, in most cases, lies within the peritoneal cavity, the operation for its evacuation demands an incision through the peritoneum. In the earliest operations it may be desirable to first dissect the peritoneum from the iliac muscle, and then to incise it somewhere in the false pelvis. If the abscess has attained a considerable size it may be preferable to cut directly through the intervening tissues, and then avoid the devious channel, with the associated tearing of the subperitoneal tissues. The terms direct and indirect laparotomy seem to indicate more clearly the nature of the operation to be performed. The danger of a direct laparotomy, even if the normal peritoneum is exposed in order to reach the pus cavity, seems often exaggerated. Dr. Elliot's case suggests that the disturbance may be comparatively slight, and Dr. Homans's experience is confirmatory.

In the classification made by Dr. Bradford there

seems to me no question as to the desirability of a laparotomy in the last three groups. In the second and third groups, especially the former, the direct method might prove preferable to the indirect laparotomy. In the fourth group direct laparotomy is likely to disclose more, as are exploratory incisions, than the indirect method of operating.

The question which seems to me most important in the future relates rather to the advisability of an operation in the first group of cases. In this class are included not a few which end fatally, with premonitory chills and jaundice, indicating a portal thrombo-phlebitis, or multiple abscesses of the liver. The peritoneum may be perforated and suppuration extend into the post-cecal tissue, or into the general peritoneal cavity. The tumor is always a source of danger, and must be watched with great anxiety. If it is easily reached it seems wiser to drain it, even if it has no considerable size and there are no urgent symptoms, than to risk the possible complications which are so serious and often so sudden.

Dr. CABOT said: I think that I should agree in almost every point with the rules which Dr. Bradford and Dr. Richardson have drawn, and they cover most cases that are presented to surgeons for decision. They do not, however, it seems to me, apply fully to cases at the onset of the disease.

As has been shown, the history of these patients is of a sudden seizure with ordinarily severe pain in the right iliac region, or over the whole abdomen. Within twenty-four hours the abdomen, or that portion of it about the ileo-caecal region may be much distended, tympanitic, and very sensitive to the touch.

If the expectant plan is pursued, and opiates are administered, we shall find that, in a large proportion of cases the pain and swelling presently show a tendency to localize themselves, the area of tenderness steadily diminishes, and a tumor is made out, which gradually grows smaller, and finally disappears. In a case like this, and such are very common, it would be manifestly improper to subject the patient to the risks of an operation, and yet at the outset the symptoms may be very serious. After a few days of improvement in a case of this sort we may have again an exacerbation of this disease, and the tenderness again becoming more considerable, and showing a tendency to spread over the abdomen, an operation becomes imperative, and we may now count upon pretty certainly finding an abscess at the bottom of the trouble.

A physician, therefore, in care of a case of appendicitis, which he is treating on the expectant plan, should watch it, as it were, with his knife in his hand, ready to interfere at once on the appearance of threatening symptoms.

Of the cases which remain localized in the region of the ileo-caecal valve, a certain large proportion tend to get well, as I have said. The fibrinous exudation disappears. If an abscess has formed it may become reabsorbed, or it may discharge itself through the perforated appendix, or by rupture into an adherent coil of intestine. Occasionally, however, rupture takes place into the bladder, or into the peritoneal cavity.

The danger attendant upon the discharge of pus in either of these last two directions should lead us to regard with great suspicion a tumor which does not quickly disappear, and if it remains long stationary, or if it shows any tendency to increase in size, it should

be operated upon in the manner described by Dr. Bradford as extra-peritoneal.

In another class of cases the disease shows a tendency to spread over the abdomen from the first, and does not, after the first onset, subside into the right hypochondrium. Such cases are usually accompanied by profound constitutional disturbance, and should be operated upon early, within the first three or four days, or even sooner in critical cases.

I have seen several cases which would come under the fourth class made by Dr. Bradford. All but one of these were seen, unfortunately, before the surgical treatment of the disease was understood as it is now. The patients who were not operated upon all died, as did also one seen last year, in whom I opened the peritoneal cavity.

In this case, of a vigorous man, the trouble came on acutely, but its exact nature and locality was somewhat doubtful. It was the general opinion of those who saw him that he had probably fecal impaction with consequent obstruction. I finally decided to operate, and going out to his room found him having a profuse fecal discharge. This looked as if the bowels had overcome the obstruction and interference was postponed.

On the following day his symptoms, instead of being better, were worse, and I then operated, making the incision in the right linea semilunaris, which seemed to me to give the easiest access to the cæcum, and also to afford an opportunity to make out the diagnosis if an unexpected condition of things existed. The incision opened immediately upon an abscess among the loose coils of intestine. It extended so far round towards the back that I made a counter-opening just in front of the quadratus muscle, and put a drainage-tube through. The patient continued to fail, however, and died about twenty-four hours after the operation. The autopsy showed a perforated and sloughing vermiform appendix as the starting-point of his trouble.

The operation in this case was done too late. If we had operated two or three days earlier, he would have stood a fair chance of getting well; and the diffused character of the pain with no tendency to localization, should, as I now look back upon the case, have led us to a speedy operation.

The only other case that I have lately operated upon, was a chronic one, and the operation simply consisted in opening an abscess above Poupart's ligament, which had its origin undoubtedly in a perforating appendicitis.

In a third case, referred to by Professor Fitz in his interesting paper, I dilated a sinus just above Poupart's ligament to provide for the freer escape of pus from a suppurating cavity, and on the following day the appendix, perforated by several openings, was protruding about one and a half inches from the wound.

The ulcerations in this case were probably tuberculous, and the patient died of phthisis some months later.

In regard to the best place for the incision, each case must be decided for itself. If I believed a general suppurative peritonitis to have started, I should open the general peritoneal cavity, as in the case first reported. Also in a case of great doubt in which the condition could not be made out, I think one could act more intelligently through an anterior abdominal incision than by groping more or less blindly behind

the peritoneum. In other cases I should prefer the extra-peritoneal incision.

As to the danger of evacuating pus through the abdominal cavity, it is, I think, less than many suppose. About a year ago in a case of pyo-salpinx in which the Fallopian tube was so firmly bound down that it did not seem possible to strip it out, I opened the abscess and introduced a drainage-tube which was brought out at the lower part of the abdominal incision. In this case, although the tube lay through loose intestines there was no infection of the general peritoneal cavity.

DR. O. W. DOE reported a

CASE OF PERITYPHLITIC ABSCESS, BURSTING THROUGH INTO THE INTESTINE. RECOVERY.⁴

DR. WHITTIER said: I don't know that I can add anything to the extremely interesting discussion that has taken place, except by briefly citing a case that is in Dr. Warren's wards now. A man of good habits, twenty-eight years of age, had been taken with pain in his bowels, and as he had chills and well-marked indication of heat, pus formation was considered to be complete. But as the symptoms were not particularly urgent, and there was no evidence of extension and formation of general peritonitis, it was decided to temporize. For ten days the improvement was progressive, and for three days longer the patient remained quiet, when suddenly pain developed in the right chest and right hypochondrium.

Physical examination showed that the lower right chest was entirely flat. The respiratory murmur was absent, and there was evidence of compression of the lung on that side. Aspiration was done, and forty-eight ounces of extremely offensive pus was removed. He came to the hospital, and I noticed that the symptoms became more urgent. Dr. Warren was asked if he would see the patient with reference to operation. Operation was done, and two quarts of extremely offensive pus were removed from the cavity. The diagnosis in this case had been typhlitis and peri-typhlitis, with probable perforation of the appendix, formation of hepatic abscess dependent on the pus formation low down, a perforation of the diaphragm, with discharge of the hepatic abscess into the pleural cavity. It seems to me to illustrate the dangers of delay in these cases.

DR. HARRINGTON said: I have seen two cases that might be classed under the fourth heading. The case to which Dr. Elliot refers, was one which has been described by Dr. Vickery. The diagnosis had been made upon the second or third day after excruciating pain. There was no tumor but great distension. On the seventh day a small hard mass could be felt by the rectum.

The patient's condition was then bad. It grew worse for two days, when I saw the patient. Under ether I could feel the mass. It could be barely touched by the finger. It seemed to point to a larger collection higher up. The symptoms were so severe that it seemed to me that there must have been a large collection of pus near the seat of the appendix. There was very great distension, and that was one of the reasons why I hesitated about making an incision. I thought that by making an extra-peritoneal incision I should discover this mass lower down. An incision was made on the outer third of the crest of the ilium, following down along Poupart's ligament.

⁴ See page 96 of the Journal.

After pushing away the peritoneum for a considerable distance, I reached no tumor, and I found nothing until the hand was well down in the true pelvis. At that time I was certainly four inches downward from the incision. Then with Dr. Vickery's finger in the rectum, this small mass could be felt between our two fingers. Its size was about that of a walnut. A trocar was inserted, but no pus was found. The operation had required quite an amount of time. The patient's condition then, as a result of the operation, was very poor, and it did not seem wise to go on. The pressure against the peritoneal wall, as I pushed my hand was very great. I did not think it right to make any further attempt. I think the patient would have died on the table.

On the following day the patient was in a collapsed condition. The next day he was improving, and gradually grew better. Three weeks later the patient was transferred to the hospital, and while there, this tumor which had been felt in the rectum grew larger, and finally broke through into the rectum. There was a discharge of pus, and the patient gradually improved and is now well.

The second case was one in which no diagnosis had been made. Dr. Whittier saw this case, and made, I think, a diagnosis of general peritonitis, from some uncertain cause the symptoms pointed to some trouble in the region of the liver. The friends did not act upon the advice of Dr. Whittier, and when I saw the case the following day, the patient was almost moribund, with a pulse of 130.

Nothing could be felt either by rectum or by abdominal palpation, but it seemed so important to do something that I made a central incision, and on putting my hand into the right iliac fossa I found quite an amount of pus. The patient came out of the ether and expressed herself as relieved, but died in four or five hours.

Dr. E. W. Cushing: I have had four cases of the fourth class, which have been reported at different times. The last I operated upon, a little boy, died.

In regard to postponing the operation. The fall of temperature is absolutely fallacious, it seems to me. A person's temperature may come down nearly to normal, and yet the process go on. There was one case, in which Dr. Cheever may remember making the autopsy with me, where the boy's temperature came very nearly to normal, and he was walking about within an hour of the time he died. In another case, that Dr. Ellis saw with me, he did not think that the case was pressing, and he died within three hours.

There was a woman brought into the hospital a little while ago with symptoms of peritonitis. She lived along about a fortnight, and used to sit up. One day she lay down and died within twenty minutes. The whole abdomen was filled with pockets of pus in among the intestines. It seems to me that when the diagnosis is made it is a question whether a temporary amelioration of the symptoms should lead us to delay when on other grounds it seems necessary to operate.

Dr. Whittier: I would like to say in reference to the case of Dr. Harrington, that I saw the case on the tenth day, and urged that Dr. Harrington be immediately sent for. The delay which he speaks of was occasioned by the delay in acquiring the consent of the patient's friends. The case I cited was seen after the symptoms of typhilitis had almost entirely

disappeared, and at that time the only question was what the pleural accumulation consisted of. A few days afterward the attending physician aspirated and found forty-eight ounces of offensive pus. The second operation was done in the hospital by Dr. Warren.

Dr. KINGMAN: I would refer very briefly to a case coming under my observation within a few weeks, leaving the fuller report to the gentleman who subsequently performed the operation. The patient was taken sick on Tuesday, was admitted to the St. Elizabeth's Hospital on Friday afternoon, was seen by several gentlemen in consultation on Saturday, and was operated upon by another member of the staff on Sunday morning, the patient being at that time transferred to his care.

The symptoms from the time of admission to the moment of operation had shown progressive amelioration, the temperature on Sunday morning being only 100° and the pulse 90, and yet the presence of the tumor indicated the necessity for operation. Death occurred in thirteen hours, of shock, and the autopsy, performed the following day, revealed the following interesting and instructive condition of affairs. There existed over the appendix a large cavity there being no distinct walls, but merely a gluing of intestines and omentum, the adhesions easily breaking down before the slightest pressure of the finger. The omentum was thickened to nearly three-fourths of an inch, and was gangrenous over a space as large as the palm of the hand. The appendix was sloughing and perforated by ulceration.

This case not only shows the rapid course of the disease and the danger of delay, but it illustrates the uncertainty of the symptoms as an indication of the severity and progress of the disease, and as a guide in deciding with regard to operation.

Dr. WARREN said: I will briefly relate one experience, and that is a case interesting from the point of view of differential diagnosis. The case had all the symptoms of perityphilitis; was seen in consultation with Dr. Fitz, and was operated upon by me. The pus was drained, the patient lived for some time, and we thought we had a case of abscess of this sort. At the autopsy it turned out to be a circumscribed peritonitis, resulting from abscess of the liver. The lobe of the liver was drawn down into that neighborhood, and apparently became adherent. There had been a chronic dysentery, which had evidently given cause for the hepatic abscess. Therefore there may be symptoms of this disease simulated by other diseases.

— Mme. Boucicault's legacy of \$4,000,000, to which we referred in a previous number of the JOURNAL, for the foundation of a hospital for the poor of Paris, is imperilled, we learn, through a condition which she attached to it namely, that the nursing should be done by the Sisters of Mercy. The municipal council of Paris has voted to substitute trained nurses for the sisters, in the hospitals under their control, which action brings them squarely in opposition to Mme. Boucicault's conditions. It is to be hoped that in this case they will not allow consistency, however great a jewel, to work the default of this great bequest. Public sentiment in such a case would doubtless turn against lay-nursing in general through exasperation at the expensive persistency of its support.

THE BOSTON
Medical and Surgical Journal.

THURSDAY, JANUARY 26, 1888.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States and Canada; \$6.00 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 94 Boylston Street.

All letters containing business communications, or referring to the publication, subscription or advertising department of this journal, should be addressed to the "Manager of the Business Department," Medical and Surgical Journal, 94 Boylston Street.

Remittances should be made by money-order, draft, or registered letter, payable to

CUPPLES AND HURD,
94 BOYLSTON STREET, BOSTON, MASS.

SURGICAL INTERFERENCE IN PERITYPHLITIS.

THE subject of operative treatment of perityphlitis occupies a large portion of this number of the JOURNAL, as it has occupied the thoughts of many of its readers for the past few years. The profession is, to-day, on the alert to recognize cases of suppuration in the region of the appendix cæci, and is agreed upon the necessity of evacuating pus, when formed in that vicinity.

But the more attentive study to which these cases have been subjected has brought into prominence a series of cases in which suppuration fails to take place, or, at least, in which spontaneous recovery occurs, and these cases occur with sufficient frequency to render it impossible to adopt the simple rule of operating in every case. It is evidently an exceedingly delicate question to decide in many cases. An incision external to the peritoneum cannot be a very serious affair; but yet it must necessarily add something to the risk in delicate subjects, and no one would willingly add even a trifling risk to such cases, if it is possible to recognize the cases which will recover without suppuration.

A still further element of uncertainty is also added by the demonstration that certain cases exist in which the rupture of the appendix must take place into the peritoneal cavity, and can only be reached by a peritoneal incision.

The papers in to-day's JOURNAL present most clearly the difficulties in the way of deciding upon the proper course of treatment. No class of cases can give the attendant greater cause of anxiety, or call for more careful watching, than expectancy may be superseded at the critical moment by active interference. The proposition to always attack the deposit of pus by a laparotomy is somewhat startling to more conservative individuals. It is, perhaps, a fair enough rule for men who have become habituated to intraperitoneal manipulations. In the hands of practiced ovariotomists it would undoubtedly yield good results, but the individual whose surgical practice is

limited cannot open the peritoneum with equal assurance of a fortunate result.

The differing anatomical conditions, which cannot be known beforehand, indicate different modes of procedure in the desperate cases; and for the present, at least, the conclusions in the paper of Dr. M. H. Richardson will commend themselves to the careful practitioner.

ON THE RISE AND DEVELOPMENT OF EPIDEMICS.

IN 1841 Sir James Y. Simpson, in his "Notes on Leprosy in the British Isles," spoke of the analogy between the species of infectious diseases and the species of animals and plants, and made the assertion that as the individual species of plants and animals inhabiting the various regions of the earth have again and again changed, "so there are strong grounds for believing that in regard to our own individual species alone, the diseases to which mankind are subject have already undergone, in some respects, marked changes within the historic era of medicine.

A writer in a recent number of the *London Quarterly Review* takes up the subject from this standpoint, and argues that the rise, development and extinction of successive new types of widespread or national sickness "has been a more every day and noticeable event than the origin of species in the animal and vegetable kingdom."

The English sweating sickness (*febris miliaris*) came and went between the years 1485 and 1551. It broke out suddenly in August, 1485, among the troops of the Earl of Richmond (afterwards Henry VIII), within four weeks was raging in London, and had overspread the entire country. It struck down hundreds as by a blow. The onset was usually in the night, with a chill followed by a hot fit. Those stricken labored under oppression at the heart and in the breathing, sickness of the stomach and headache. In the course of a few hours the skin becomes turgid, and a profuse sweating began, to subside gradually after twenty-four or forty-eight hours, or to end in total collapse and death in a state of coma. Epidemics were very frequent for the space of three-quarters of a century, when it disappeared from England never to revive.

This sweating sickness bore such a marked resemblance to the "snette miliare" of Picardy that there can hardly be a question that it is essentially the same species of disease, although the modern form has hardly ever been extensively disastrous, but is rather endemic. The *Quarterly Reviewer* puts together some striking facts which, in his estimation, go to connect the English sweat with the Picardy sweat. The English sweating sickness came in the train of the Earl of Richmond's foreign levies, with which he defeated Richard III on Bosworth field. These French levies, called by Shakespeare, in his Richard III, "the scum of Bretagne, and base lackey peasants —"

"Whom their o'er-cloyed country vomits forth
To desperate ventures and assured destruction —"

are traced by the reviewer to their homes in the very region where the "*suetie des Picards*" showed itself as an indigenous disease more than two hundred years later. His reasoning, in brief, is as follows: Conditions of living that engendered an endemic disease about the year 1718 had been going on long before. The peasants and vagabonds of that region, when taken to England in 1845, either under the sudden change of condition developed this disease in their own bodies, or, more probably, the mere effluvia or exuvia of their bodies caused the disease in others. If the disease was merely potential in them at that time, it may be said to have been at the same date merely potential also in their homes on their native soil. That which came to sudden development in 1485 by contact with another nationality came also to maturation in 1718, after two hundred years of slow fermenting amidst the original conditions.

The history of Asiatic cholera is traced by the writer, and an analogy between it and the "sweating sickness" is suggested. Cholera broke out in the lower valley of the Ganges in the spring of 1817, and extended throughout lower Bengal. In 1818 it spread over the greater part of India, and henceforth the disease figures regularly among the indigenous maladies of the country. More particularly the lower basins of the Ganges and Brahmapootra have come to be looked upon as the "endemic area" of cholera. The disease now appears regularly every season, as if it were a fruit of the earth, and, although it is more destructive some years than others, the annual mortality from it in Lower Bengal is always considerable.

The reviewer very ingeniously traces the rise and evolution of this dire disease to excrementitious pollutions of the soil, "due, first of all, to the personal habits of the villagers, which are the cause of that *odor stercoreus* that we read of around a Bengali village. . . . There is also a certain peculiar decomposition of human exuvia in the soil, caused by the porous character of the surface layer of alluvium, or of laterite; the presence of sub-soil water close to the surface all over Lower Bengal, and the flooding of the ground during the rainy months of June, July, August and September, and the drying of it at other seasons. The alternating seasons of rain and drought cause regular movements of the sub-soil water up and down, movements which are known to favor decomposition of the organic matters in the soil, and to favor their exhalation into the air."

In reply to the questions: "If these are the old characteristics of soil, season, and natural habits that have been present in Bengal for generations, why should cholera have apparently become epidemic there only within the last seventy years?" "How is it the excrementitious fouling of a vast tract of river basin and delta has at length made inveterate what had previously been intermittent, and has made diffusive what had never before been heard of beyond India?" the writer advances the supposition of a "cumulative action," or of "gradual aggravation, or, in a figure,

of provocation beyond the limit of endurance." "Whatever," he says, "may have brought about the crisis in the early part of this century, it is worth keeping in mind that the number of persons supported on the soil of Lower Bengal may be taken with good reason to have increased greatly within the period of English rule; that the increase has been in the original village communities, and not in large towns, and that the heart of the endemic area of cholera is remarkable among the provinces of the globe for the enormous rural population that it carries, a population that is, in many places, seven hundred to the square mile, and in some places nearly a thousand."

In the same manner the writer accounts for yellow fever, which is "not a form of mere climatic or malarial remittent fever," but "whose affinities are really with typhus fever." "It is typhus with a very remarkable difference, a typhus of the soil and mud of certain harbors of the new world." He sets aside the "rotten wood hypothesis," the "bilge water hypothesis," as untenable, to adopt the brilliant generalization of Audonard, which connects yellow fever with the over-sea traffic in African negroes. "The concurrence of testimony from all sides—from the clinical type, or affinities of the disease, from the geography and the history, from ethnology, and from ethics—connects yellow fever with the African slave trade in as startling a manner as if some hand had written it for us on the wall."

Another endemic disease, pellagra, which is very prevalent in Northern Italy, certain provinces of Spain, etc., and limited to the poor peasantry, is regarded as the slow, insidious and cumulative effect of a staple diet of bad maize, of bread and porridge made from the poorer sorts of Indian corn grown in soils where it will not ripen perfectly, gathered in a wet state, badly husbanded, apt to decompose in the grain or flour, and still more apt to spoil in the ill-baked loaves of bread."

Other diseases, endemic and epidemic, are considered in the same spirit, and an attempt is made to show their dependence on complicated local causes and conditions: leprosy, beriberi, black death, famine fever, typhoid malaria, goitre, the Peruvian wart. The problems of disease species, of their origin and reproduction, the reviewer says, are not so simple as many people seem to imagine. "Before we come to the germ we must settle the individual, unless, indeed, we summarily make an end of an old difficulty and decide once for all that the egg does really come before the hen. The medical profession has not only plenty of work before it of the ordinary biological or physiological kind, it has also philosophical problems assigned to it which are unique in their difficulty. Should it ever cease to deserve the good name of a liberal and learned profession it will not be because the subject matter of its calling does not demand the exercise of the highest qualities."

This reasoning is evidently not wholly sanctioned by the best recent biological thought and study.

BOVINE DISEASE AND SCARLET FEVER.

It will be remembered¹ that two years ago an epidemic of scarlet fever prevailed in Northwest London which was tracked by the medical authorities to a milk farm at Hendon. The disease was shown to prevail almost exclusively among families that had obtained their milk-supply from this farm. On investigation it was found that some of the cows at this locality were suffering from an infectious disease of the teats and udder. Dr. Klein of the Brown Institution, Dr. Cameron the health officer of Hendon and Mr. Power representing the Local Government Board, gave careful attention to the matter, and with due caution expressed their opinion that the bovine disease was essentially identical with scarlet fever. Dr. Klein, moreover, found a micrococcus which he declared to be common to both affections. He also made many inoculation experiments on calves with the blood of scarlet-fever patients, and with the products of the culture of the "micrococcus scarlatinae," and succeeded in inducing a disease which bore a marked resemblance to the Hendon cow disease.

Professor Crookshank, of Edinburg, has since reinvestigated the whole matter. His paper appears in the *Lancet*. His investigations do not bear out the conclusions previously formulated by Drs. Klein and Cameron. He has found the micrococcus described by Dr. Klein, but he believes it to be a septic micro-organism. As for the nature of the disease prevailing among cattle at Hendon and surrounding districts, it is, he finds reason to believe, simply the true *Jennerian cow-pox*, and in no sense a scarlatinous affection. This conclusion, if accepted, leaves the origin of the north-west end epidemic, and its relation to the milk-supply, as far from a solution as ever.

CAPITAL PUNISHMENT BY ELECTRICITY.

THE Commission appointed last winter, consisting of Elbridge T. Gerry, Matthew Hale, and Dr. Alfred P. Southwick, to investigate and report upon the most humane and practical method of capital punishment, have just presented the results of their labors to the New York Legislature in the form of a pamphlet of about one hundred pages.

A circular was first prepared soliciting views upon the present mode of punishment, and suggestions in regard to some more humane method. Suggestions were also invited regarding the disposition of the body of the person executed, with a view to increasing the deterrent effect of capital punishment. The circular was widely distributed, especially among judges, district attorneys, sheriffs, and physicians; and, after a careful consideration of the two hundred replies which were received, and much outside inquiry and study, the Commission decided in favor of electricity. They suggest that the criminal to be executed be placed in

a chair having metallic plates at the head and foot rests connected with electrodes, and that all executions shall take place at one of the three State prisons located at Sing Sing, Auburn, and Dannemora.

Various changes are recommended in the present laws in regard to criminals condemned to death.

The report provides that, in regard to the infliction of the punishment of death, it must in every case be inflicted by causing to pass through the body of the convict a current of electricity of sufficient intensity to cause death, and the application of the current must be continued until the convict is dead. The execution must take place within the walls of the State prison designated in the warrant, or within the yard or inclosure adjoining. It is the duty of the warden to be present at the execution, and to invite the presence of a Justice of the Supreme Court, the District Attorney, and Sheriff of the county in which the conviction was had, together with two physicians and twelve reputable citizens. Besides one, or, at most, two clergymen, and seven assistants or deputy sheriffs, no persons other than those mentioned shall be permitted to be present.

Immediately after the execution, a post-mortem examination of the body of the convict shall be made by the physicians present at the execution, and their report in writing, stating the nature of the examination made by them, shall be annexed to the certificate, signed by all the persons witnessing the execution, that the sentence was duly carried into effect in accordance with the requirements of the law.

After the post-mortem examination, the body shall be delivered by the warden for the purposes of dissection to some public hospital or incorporated medical college within the State; or the body may be interred in the graveyard or cemetery attached to the prison, with a sufficient quantity of quicklime to promptly consume it. In no case shall the remains be delivered to any relative or friend; and no account of the details of any such execution, beyond the statement of the fact that the convict was, on the day in question, duly executed according to law at the prison, shall be published in any newspaper.

THE OBSTETRICAL SOCIETY OF BOSTON IN THE WAR OF THE REBELLION.

THE Obstetrical Society of Boston has recently printed for private distribution a sketch of the services of its members in the War of the Rebellion. The paper was prepared by Dr. George H. Lyman, one of the founders of the Society, and who was himself in active service from April, 1861, to November, 1865.

It would not seem that a society of obstetricians would be likely to engage in military service, professionally or otherwise; yet the record shows that with a membership limited to thirty, this Society furnished fourteen commissioned officers; and eleven others rendered much gratuitous service as inspectors for the

¹ Journal, Vol. CXIV, p. 601, Vol. CXV, p. 115, Vol. CXVI, p. 613.

Sanitary Commission, as contract surgeons, and as examiners of recruits. The Society was organized only four months before the war, and some were not members at the time of their service, but joined the Society subsequently. But of the entire membership, which has numbered only sixty up to the present day, twenty-five is a large proportion to have given their services to their country.

Of the fourteen commissioned officers, ten served on the medical staff: seven in the army, three in the navy. The other four served in the arm of the service which made wounds, not dressed them. One was a captain in the line, was wounded in the battle of the Wilderness and suffered the horrors of Libby Prison. One enlisting as private reached the rank of captain and served as brigade adjutant. Another, while yet a medical student, enlisted as a private, rose to the rank of lieutenant-colonel, and saw much active service. One original member of the Society, after a few months of medical service, "tired of curing wounds and preferring to make them," secured a captain's commission in the line, rose to the rank of lieutenant-colonel, and fell mortally wounded at the head of his command after a desperate cavalry charge.

We are ever glad to honor patriotic service on the part of any one; but it gives us a peculiar pleasure to see placed in enduring form the simple records of the devotion of the medical profession — whether it be to their country in time of need or to suffering humanity in the ordinary duties of daily life.

MEDICAL NOTES.

— Dr. Auvard, of Paris, has succeeded to the editorship of the *Archives de Tocologie*, which was founded in 1874 by Professor Depaul.

— We learn from a contemporary that a movement is on foot looking to the erection of a new crematory, in or near New York, wherein bodies are to be incinerated by electricity. The scheme is regarded as a feasible one, and, it is believed, will do much towards removing the prejudice existing against cremation by the elaborate method practised in Pennsylvania, Long Island, and elsewhere. The electrical crematory is the invention of a Sicilian; the heat is generated by a dynamo of a pattern similar to that used in the incandescent-light system, and succeeds in evaporating, as it were, the bodies, till nothing remains.

— Prince Chun, the father of the reigning emperor of China, who was reported as dead by the press cable despatches some weeks ago, is not dead, but is said to be merely suffering from a passing indisposition, due to a treatment by powdered otter's liver, to which he had been subjected by his native medical attendant. An English physician of the name of Dr. Manson has now been summoned from Hong Kong to take charge of the case of his imperial highness, this being the first occasion in which a foreign doctor has ever attended a member of the imperial family of China.

— M. Carnot, President of the French Republic, on the last day of the old year, made a round of inspection of the various Parisian hospitals, in the course of which he decorated with a knight's ribbon Mlle. Nicolle, the school mistress at the Salpêtrière, who is now in her thirty-sixth year of service, and a Sister of Charity in the military hospital of Val-de-Grâce.

— An industrious statistician has recently contributed to a medical journal at Lille, the results of an analysis of one thousand labors, with the precise hour at which delivery took place. He reports, says the *British Medical Journal*, that forty-five per cent. of the labors terminated between 8 A. M. and 8 P. M., and fifty-six per cent. between 8 P. M. and 8 A. M. Pushing the inquiry a step further, he found that twenty-three per cent. terminated between 6 A. M. and midday; twenty-two per cent. between midday and 6 P. M.; twenty-seven per cent. between 6 P. M. and midnight, and 54.1 per cent. during the night — that is to say, between midnight and 6 A. M. These figures only apply to normal labors, in which nothing interfered with the physiological course, so that they go far to confirm the popular notion which admits the greatest frequency of delivery at night, "conception generally taking place at about that time."

— Lord Grimthorpe, in a recent somewhat florid communication to the *London Times*, sets the number of homeopathic practitioners in Great Britain at 10,000. That a "round number" does not in this case any more than proverbially express mathematical correctness is shown by the following figures, quoted from the *British Medical Journal* in answer to a correspondent who wishes to know if the sect is increasing: The *British Homeopathic Medical and Pharmaceutical Directory*, for 1875 (London: Homeopathic Publishing Company), contains in a "List of Qualified Physicians and Surgeons Practicing Homœopathy in England, Scotland, and Ireland," 269 names, and in a supplementary "List of Practitioners Holding Degrees from Foreign Universities and Colleges whose Diplomas cannot be Registered under the Medical Acts," 9 names, making a total of 278 names. The *British Homeopathic Medical Directory*, for the year 1887 (editors and publishers, Thompson & Capper, homeopathic chemists, Liverpool, etc.), contains in a "List of Qualified Physicians and Surgeons Practicing Homœopathy in England, Scotland, and Ireland," 258 names; there is no supplementary list. The preface contains the following paragraph: "Many inquiries having been received relative to the omission of well-known names, it is necessary to state that in almost all cases such names have been omitted at the individual's own request."

— Dr. F. E. Hayward, writing in the *British Medical Journal*, December 24, 1887, says that sodium fluosilicate, the new antiseptic which has recently been coming into use, promises to prove an equally effective and much safer agent than corrosive sublimate in midwifery practice. It is but slightly soluble in water, only to the extent of about two-thirds

per cent. at 60° F., that is, a pint of water will dissolve about fifty grains. It should be used in saturated solution. A few powders of fifty grains each will form but a trifling addition to the weight of the midwifery bag.

—The *London Medical Gazette*, commenting on the paper on the transactions of the Epidemiological Society of London, by Inspector-General Lawson, on "Outbreaks of cholera in ships carrying coolies from Calcutta, and in other ships with troops," in which that gentleman claims that the disease has originated at sea from "pandemic waves," points out that the ships visited by such "waves" are all southward bound, and come from localities that have been recently infected, while no such waves have in a single instance struck vessels, even though in just the same latitudes, *northward* bound from a port in which cholera did not prevail. It also suggests that the pandemic waves find it hard to catch steamers, as in the two cases mentioned the steamers (from cholera infected ports) had had time to sail much farther on their voyage than the sailing vessels before the disease overtook them. The *Gazette* epigrammatically sums up its review by remarking that "in this instance it is not the cholera but the Inspector-General that is at sea."

—Dr. Morrison, in the medical reports of the Inspector-General of Customs in China, March, 1887, says: "February 12th, a small farmer, named Ma, was brought in to me from T'ien-chia-t'un, a village about seventeen miles distant. On examination, found right eye entirely enucleated and the left partially so and utterly useless, so far as hopes of seeing were concerned. He informed me that three days previously, on the road, he had been set upon by seven or eight men, who tied his hands and feet together, and, with a copper scoop, proceeded to gouge out his eyes. He knew they had only been partially successful with one, and therefore his friends had brought him to see if I could restore it to its natural condition. His offence was that his father owed a debt of forty taels, which, at the Chinese New Year, when accounts are settled, he had failed to pay." The reporter adds that he is informed that this practice is not uncommon, and that about the same time another case occurred in the neighborhood, where the unfortunate man died from the effects of the wounds. The matter is engaging the attention of the Chinese authorities.

BOSTON AND NEW ENGLAND.

—Dr. S. H. Durgin, Chairman of the Boston Board of Health, delivered a lecture, last week, on "Hygiene" at the Young Men's Christian Union.

—The new hospital buildings in connection with the State institution at Tewksbury, Mass., which have just been completed, *within the appropriation*, stand upon the west side of the old quadrangle, and consist of two buildings, each 107 feet, 10 inches, by 36 feet, 4 inches, placed in line north and south, 50 feet apart, and connected by a glazed corridor or sun-room.

The buildings are divided into nineteen wards, varying in size from a small, single room 6 feet, 8 inches, by 12 feet, to wards 31 feet, 6 inches, by 32 feet, 6 inches, containing fourteen beds, these last being located at the extreme ends of the buildings. Great satisfaction is experienced in the working of the special apparatus for heating and ventilating the wards. The buildings were constructed under the special charge of Dr. C. I. Fisher, the architects being Messrs. Hartwell and Richardson.

NEW YORK.

—The quarterly meeting of the Westchester Medical Society was held at the Murray Hill Hotel, New York, on the 17th of January, and during the course of the proceedings, Dr. E. H. Brush, of Mount Vernon, gave a *résumé* of a recent study of bovine tuberculosis, the results of which led him to strongly oppose the inbreeding of cattle.

—The First District Dental Society of the State of New York, held its nineteenth annual meeting in the Masonic Temple on the 17th and 18th of January. Among the more important papers read was "A Contribution to the Knowledge of Tumors of the Jaw," which was the joint production of Dr. Frank Abbott, of the dental profession, and Dr. C. Heitzmann, the well-known pathologist.

—The annual meeting of the Hospital Saturday and Sunday Association was held at St. Luke's Hospital, January 16th, when the same officers were re-elected. It was announced that notwithstanding the fact that the Presbyterian Hospital had withdrawn from the Association, the receipts reported to date were even larger than those reported at the same time after the collection last year. On January 18th, the fund amounted to \$45,725. At a meeting of the New York Presbytery, held January 10th, it was given out that since the 23d of December, the Presbyterian Hospital had received \$31,000 in subscriptions.

—At the annual meeting of the New York Post-Graduate Medical School and Hospital, held January 17th, the following officers were elected: President, Dr. D. B. St. John Roosa; vice-president, Dr. William A. Hammond; treasurer, Dr. W. O. Moore; director, Dr. George H. Fox. The affairs of the institution were reported to be in a flourishing condition and the number of matriculants to be larger than ever before.

—The New York State Academy of Veterinary Service and Comparative Pathology, held its annual meeting and dinner January 19th, when Dr. J. M. Heard was elected president, and Drs. E. S. Breder and H. E. Earl, vice-presidents.

—The Board of Pharmacy, of which Dr. Cyrus Edson is president, has of late been doing good work by its vigorous action in securing the enforcement of the law forbidding the sale of drugs and poisons by persons not properly qualified to do so, and a number of arrests have been made on the charge of its violation.

— At the annual meeting of the New York County Medical Association, held January 16th, the following officers were elected for the ensuing year: President, Dr. J. R. MacGregor; Vice-President, Dr. C. S. Wood; Recording Secretary, Dr. Frank Grauer; Corresponding and Statistical Secretary, Dr. J. W. Small; Treasurer, Dr. C. Ellery Denison; Member of the Executive Committee, Dr. C. A. Leale.

Miscellany.

COMPARATIVE STATEMENT OF MORTALITY IN BOSTON IN 1886-87.

THE Board of Health has compiled and published an interesting comparative statement of the number of deaths and their causes in 1886 and 1887. The following features of the statement are herewith given:

	1887.	1886.
Total number of deaths from all causes	10,975	9,268
Population	400,000	400,000
Mortality-rate per 1000 inhabitants	25.18	23.17
Total from zymotic diseases	1,993	1,644
Percentage of deaths from zymotic diseases to total mortality	19.7	17.73
Total deaths of children under one year	2,512	2,110
Total deaths of children under five years	3,462	2,186
Percentage of deaths under five years to a total mortality	36.3	34.37
Percentage of deaths from diarrhoeal diseases to total mortality	7.2	7.60
Diphtheria	246	329
Measles	119	36
Scarlatina	105	81
Small-pox	—	—
Typhoid fever	183	135
Pneumonia	735	778
Violent deaths	412	371

TETANUS FROM USE OF THE STOMACH-TUBE.

THE *New Yorker Med. Presse*, December, 1887, brings to us, through several intermediate channels, the report of an interesting case of death following the use of an oesophageal or stomach-tube. The patient was a man, forty-eight years old, who had been treated seven years before for stricture of the pylorus. At the time when he came again under treatment, he was suffering with flatulence, pain, progressive weakness, and frothy vomit. His stomach was found to be dilated. It was decided to wash out his stomach, and a tube was passed down his oesophagus. Hardly was this done, when he became faint, and the instrument had to be removed. Two hours afterward his jaws became stiff, he could not open his mouth, his arms became rigid, pronated and flexed, and his thumbs were flexed in his palms. He retained his consciousness; but was in a profuse sweat. Gradually all the muscles of his limbs and trunk became rigid; his temperature rose to 113° , and he died cyanosed.

At the autopsy the diagnosis of stricture of the pylorus and dilatation of the stomach was confirmed, and no lesion of the mucous membrane of the oesophagus could be found.

The presumption is that this was a case of tetanus, caused by the mere impression of the operation. It is analogous to a few other recorded cases in which tetanus occurred, for which there seems to be no explanation, except that it was largely due to a mental impression. A number of these cases are precisely

like certain cases of so called hydrophobia, in which no material injury, no infection can be supposed to have given rise to the symptoms, and in which the phenomena are only explicable by the assumption that they were due to a pure psychosis.— *The Medical and Surgical Reporter*.

Correspondence.

DR. NORMAN BRIDGE AND THE COOK COUNTY HOSPITAL.

CHICAGO, January 10, 1888.

MR. EDITOR, — The *Journal* of the 5th inst. is in error in saying that I had "refused to treat as charity patients persons able to pay, but admitted to the (Cook County) hospital under political favoritism, and for this refusal was severely criticised by the *Chicago Tribune*." The hospital incident consisted simply in my sending a private patient to the hospital to board as a pay patient while I made a surgical operation for her, for which I received the usual fee. This was a convenience for the patient, and was in pursuance of a regulation of the hospital long in vogue. The personal malice of the *Tribune*, growing out of other and chiefly political considerations, led that paper to charge — among the manifold wickedness it has attributed to me — that I had violated a rule that applies solely to the usual hospital or charity patients, that is, that doctors should serve without fee or reward. This rule was never violated to the breadth of a hair by myself, or by any other attendant so far as I know.

Very respectfully,
NORMAN BRIDGE, M.D.

SPEEDY RECOVERIES AFTER CHILD-BIRTH.

FORT GIBSON, INDIAN TER., January 16, 1888.

MR. EDITOR, — In the discussion of Dr. F. W. Draper's paper on the "Obstetrical and Legal Relations of Infanticide," by the Obstetrical Society of Boston (*Medical and Surgical Journal*, Vol. CXVIII, No. 1, p. 14), Dr. Farlow, in "illustration of the apparent impunity with which women often resume their daily affairs soon after labor," mentions the case of a washer-woman, who, between wash-days, gave birth to twins, and then resumed her work — he does not say how soon after the first wash-day the twins were born.

In my own experience there are two cases — examples of many others — which illustrate this point with much exactness: While on duty at Fort Bennett, Dakota, some three years ago, the Sergeant of Indian Scouts (an educated half-breed) came after me to attend one of his children. I went to the scout's camp, and found a child, about fifteen hours old, in convulsions. The mother was sitting up, fully dressed, and had evidently been attending to her household duties. After attending to the child, I asked the Sergeant if he considered it safe to allow his wife (also an educated half-breed) to be up and about so soon after delivery. He looked at me in surprise, laughed, and said she always got up an hour or so after the baby was born; in point of fact, she had done so after each of her three preceding labors — "all her people did so." He said, on my questioning him, that after the birth of the child, she would lie in bed long enough for the after-birth to come away, and to rest a little, and would then get up and go about as though nothing had happened. The old women of the camp do all the obstetric practice; men are not permitted in or about the hut or tent at the time. This family belonged to the *Sans Arc* band of the Teton Sioux.

One morning, while at the Agency (close to the garrison), I met a young squaw with an evidently very recent accouchement in her arms — indeed, so recent, that the vernix caseosa was still on it. I asked her how old that baby

was? She answered, "one sleep," meaning that the child was born some time late in the afternoon of the previous day. The baby's face, notwithstanding the vernix caseosa, was gorgeously decorated with red and yellow paint, of which design the mother seemed quite as proud as she did of the youngster. This young woman was walking around, the baby not over twenty hours old, as strongly as though the confinement (?) had taken place a month before.

One of the officers at that post, too, told me of another instance: Some years before, just after the Sioux surrendered, a hunting party (of Indians) obtained permission from the agent to go out and hunt buffalo. This officer was detailed to go in charge, and a middle-aged squaw was detailed to pack and pitch his tepee. He said he noticed she was very large when they started, and "one day, about a week after starting, she appeared with a baby, which, she said, had been born some few hours

previously" (during the night). Her enlargement had disappeared. Lieutenant P. informs me that she struck and packed his tepee, and rode pony-back, that day's march — some forty miles or so.

It is very generally thought that the Indian women do not suffer pain in labor. This, I know, is erroneous, both from the testimony of "squaw-men" (white men married to Indian women), and from native works of art depicting their women in this interesting condition. Without exception, the pictures had the zig-zag line running down from the inner canthus of the eye, which stands, in Indian art, for tears or water. Pointing to the picture, I have asked several Indians "if the child hurts the woman much?" The reply was always the equivalent of "exceedingly; much cry!" Yours very truly,

C. N. B. MACAULEY.

Captain and Assistant Surgeon, U.S.A.

REPORTED MORTALITY FOR THE WEEK ENDING JANUARY 14, 1887.

Cities.	Estimated Population.	Reported Deaths in each.	Deaths under Five Years.	Percentage of Deaths from

Deaths reported 2,591: under five years of age 791; principal infectious diseases (small-pox, measles, diphtheria and croup, diarrhoeal diseases, whooping-cough, erysipelas and fevers) 375, acute lung diseases 324, diphtheria and croup 169, scarlet fever 67, typhoid fever 30, diarrhoeal diseases 34, measles 20, malarial fever 20, whooping-cough 14, cerebro-spinal meningitis 11, erysipelas five, puerperal fever four, small-pox (New York and Brooklyn one each) two. From diarrhoeal diseases, New Orleans nine, New York and Philadelphia eight each, Boston three, Brooklyn two, Baltimore, District of Columbia, Nashville and Lynn one each. From measles New York six, Baltimore and District of Columbia four each, Brooklyn three, Philadelphia and Boston one each. From malarial fever New York 10, Brooklyn and New Orleans four each, Baltimore and Charleston one each. From cerebro-spinal meningitis, District of Columbia three, Worcester two, New York, Philadelphia, Pittsburgh, Milwaukee, Nashville and Fall River one each. From whooping-cough, New York eight, Boston two, Brooklyn, Baltimore,

Pittsburgh, and Milwaukee one each. From erysipelas, New York and New Orleans two each, Baltimore one. From puerperal fever, New York, Boston, Pittsburgh and Nashville one each.

In the 28 greater towns of England and Wales with an estimated population of 9,244,093, for the week ending December 31st, the death-rate was 24.8. Deaths reported 4,402; infants under one year of age 1,007; acute diseases of the respiratory organs (London) 442, whooping-cough 183, measles 86, scarlet fever 84, fever 51, diphtheria 38, diarrhoea 32 small-pox, (Sheffield 24, Bristol two, Leeds and Hull one each) 28.

The death-rates ranged from 18.5 in Brighton to 33.9 in Bolton; Birmingham 24.4; Blackburn 29.0; Bradford 23.0; Hull 22.0; Leeds 25.1; Leicester 27.7; Liverpool 23.2; London 27.1; Manchester 32.5; Nottingham 28.9; Sheffield 27.7; Sunderland 21.3.

In Edinburgh 21.6; Glasgow 24.6; Dublin 36.2.

The meteorological record for the week ending January 14, in Boston, was as follows, according to observations furnished by Sergeant O. B. Cole, of the United States Signal Corps:—

Week ending	Barom-eter.	Thermometer.				Relative Humidity.			Direction of Wind.			Velocity of Wind.			State of Weather. ¹			Rainfall.		
		Daily Mean.	Daily Mean.	Maximum.	Minimum.	7.00 A. M.	3.00 P. M.	10.00 P. M.	Daily Mean.	7.00 A. M.	3.00 P. M.	10.00 P. M.	7.00 A. M.	3.00 P. M.	10.00 P. M.	7.00 A. M.	3.00 P. M.	10.00 P. M.	Duration, Hrs. & Min.	Amount in Inches.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE UNITED STATES MARINE-HOSPITAL SERVICE, FOR THE TWO WEEKS ENDING JANUARY 21, 1888.

PURVANCE, GEORGE, surgeon. To proceed to Detroit, Mich., as inspector of unserviceable property. January 11, 1888.

AUSTIN, A. W., surgeon. When relieved to proceed to Chicago, Ill., and assume charge of the Service. January 12, 1888.

GASSAWAY, J. M., surgeon. Leave of absence extended fifteen days. January 10, 1888.

GOLDSBOROUGH, C. B., surgeon. When relieved to proceed to New Orleans, La., and assume charge of the Service. January 12, 1888.

IRWIN, FAIRFAX, surgeon. To proceed to Boston, Mass., and assume charge of the Service. January 12, 1888.

CARTER, H. R., passed assistant surgeon. When relieved to proceed to Ship Island Quarantine, Miss., and assume temporary charge of the Service. January 12, 1888.

CARRINGTON, P. M., assistant surgeon. Granted leave of absence for thirty days. January 10, 1888.

GOLDSBOROUGH, C. B., surgeon. To proceed with insane section from Chicago to Government Hospital for the Insane. January 10, 1888.

HEATH, F. C., assistant surgeon. To proceed to Buffalo, N. Y., for temporary duty. January 29, 1888.

STONER, G. W., surgeon. To proceed to Wilmington, N. C., Georgetown and Charleston, S. C., Savannah and Brunswick, Ga., Fernandina, Jacksonville and Pensacola, Fla., as inspector. December 30, 1887.

SOCIETY NOTICES.

SUFFOLK DISTRICT MEDICAL SOCIETY. SURGICAL SECTION.—There will be a meeting of this Section at 19 Boylston Place, on Wednesday evening, February 1st, at 8 o'clock. Dr. F. L. Jack will report a case of "Necrosis of the Temporal Bone; Removal of the Labyrinth; Recovery." Dr. A. T. Cabot will present some "Notes on Complications met with in Hemiplegia." Dr. H. L. Burrill will show a specimen of the "Replantation of a Trephine-Button of Bone."

G. H. MONKS, M.D., Secretary.

NORFOLK DISTRICT MEDICAL SOCIETY.—A meeting for Scientific Improvement will be held at the Hall of the Roxbury City Guard, 67 Warren Street, Roxbury, January 21, 1888, at 7.45 P. M. Communications: I. "Southern California as a Health Resort." S. L. Dutton, M.D. II. "Two Cases of Erysipelas of the Pharynx." A. B. Collin, M.D. III. "Pathological Specimens." W. P. Bolles, M.D.

S. ALLEN POTTER, M.D., Secretary.

BOSTON DISPENSARY APPOINTMENTS, ETC.

At the January meeting of the Board of Managers of the Boston Dispensary, the following appointments were made: Dr. Rufus A. Kingman, physician to the department for diseases of women; Drs. Winfield B. Bancroft, William F. Temple and George E. Richards, physicians on the medical staff at the central office; and Drs. Robert W. Greenland, George E. Thompson and Frederick W. Stuart, district physicians.

Noted, that the recommendation of the superintendent to furnish medical aid at the Central Office to the deserving poor of the entire city of Boston, be adopted.

EDWARD S. GREW, Secretary.

DEATH.

Died at Fairhaven, Mass., January 15, 1888, George Atwood, M.D., M.M.S.S., aged seventy-two years.

BOOKS AND PAMPHLETS RECEIVED.

Vick's Floral Guide. 1888.

The Vermont Asylum for the Insane. Its Annals for Fifty Years. 1887.

Syphilis of the Endometrium. By T. A. Ashby, M.D., Baltimore, Md. Reprint. 1887.

Treatment of Chronic Suppurative Otitis Media. By Seth S. Bishop, M.D., of Chicago. Reprint. 1887.

FEVER AND THE USE OF ANTIPYRETICS.¹

BY J. ARTHUR GAGE, A.M., M.D., OF LOWELL, MASS.

It was my original intention to write upon the uses of antipyretics, and to compare some of the more recent drugs employed for the reduction of high temperature. I was, however, confronted at the outset with the question, what is fever?—a question that has been much discussed, and still awaits a decisive answer. But so much light has been thrown upon the subject in the last few years, that I shall venture to trespass upon your time in an attempt to answer this question as far as possible, reserving for the end of the paper a brief reference to the most important antipyretics, and an explanation of their rational use in the treatment of fever. I shall first consider the source of heat in the body, its loss from the economy, and the resultant we call temperature; next study the variations in temperature, and their mode of production; and finally, consider the phenomena of fever, and the theories as to its source.

If you expose the thigh-muscles of a dog, and, after plunging a thermometer into their substance, cause a contraction by electrical current, you get a rise of the mercury. This takes place even if the blood-supply is cut off.² If you make the contractions tetanic, the rise of temperature ceases to occur after a time, though the muscles are still capable of contracting.³ If you stimulate the chorda tympani, the temperature of the saliva is raised 2° F. above the temperature of the blood in the carotid artery.⁴ The temperature of the gland itself is also raised, though the blood-supply is cut off.⁵ Again, we find that the blood coming from a large gland, as the liver, is the warmest in the whole body.⁶ Here are evidently sources of heat, the formation of which is independent of the blood-supply, incited by nervous stimuli, and, in the case of muscles, independent of motion. Other tissues also form heat, and Foster says: "We may affirm that the heat of the body is generated by the oxidation of the tissues at large. . . . Wherever tissue metabolism is going on, there heat is being set free." But of all tissues, the muscles, both on account of their bulk and character, are, *par excellence*, the thermogenic tissues. This is true even during sleep when the muscles are quiet, the so-called condition of muscular tonic. We may thus study the muscles in our investigations upon heat-formation.

This source of heat is variable, being increased after active exercise or exposure to cold; and, if there were not some means of getting rid of heat, the body-temperature would rise to a great height, reaching the boiling point in thirty-six hours, according to one experimenter. The loss of heat takes place through the skin, lungs, urine, and faeces by evaporation, conduction, and radiation. We lose 77% by the skin, a large share going off in evaporation of sweat. Twenty per cent. is lost by the lungs, 15% being used in evaporation, and the remaining 5% going to warm the expired air. Three per cent. goes to warm the faeces.⁷

The loss of heat will depend upon the activity of the sweat-glands, the circulation, and the respiration, as well as upon the temperature and moisture of the surrounding atmosphere—these are all variable factors. Thus we have seen that the sources of heat-formation in the body are variable, that the rate of heat-loss is variable; yet their resultant, the body-temperature, is a constant, or rather, a variable within such small and well-defined limits, that it is called a constant, and is placed at 37.4° C. or 98.6° F. If we examine the temperature more closely, we shall find, according to Jürgensen,⁸ that it has a daily variation [as was shown by Dr. L. Huntress in his paper before the union meeting of Middlesex societies at Concord, July, 1887], being highest just after mid-day, and lowest just after midnight. The question at once suggests itself: what regulates the ratio between heat-formation and heat-loss with such wonderful accuracy and such rhythmical measurement? what is it that controls the body-temperature in health? what is this power that, in disease, is overthrown, giving rise to the phenomena of fever?

Let us consider now the methods of heat-formation and heat-loss, taking the latter first, because it is better understood. If a healthy person gets into a cold bed, he soon finds the temperature of the bed raised to a degree of comfort by heat that must have been given off from his own body. This process of heat-loss is going on continuously, and it is desirable to know how we can measure it. Liebermeister placed a man in a bath, and noted the rise of the temperature of the water. From this he computed the amount of heat that must have been given off from the body. But the loss to the surrounding air from the water, and the loss from the lungs, were sources of error too great to permit of accuracy. Professor Leyden, of Leipzig,⁹ performed the following experiment: He constructed a calorimeter in the shape of a copper cylinder surrounded by a water-chamber, and this surrounded by a non-conducting material. Splashes kept the water in motion, and thermometers registered its temperature. He estimated the amount of heat necessary to raise the temperature of the water 1° C. in one hour as 55 k-units (the k-unit being the amount of heat necessary to raise the temperature of one kilogram of water 1° C.). This was called the calorimetric value of the chamber. He placed the leg of a healthy man in the chamber, secured round the thigh by a double rubber collar. At the end of one hour the temperature was raised 0.12° C. Multiplying the number of heat-units (55) necessary to raise the temperature 1° C. in one hour by the number of degrees it was raised in a given case, would represent the heat given off by the leg. This gave 6.6 k-units for one hour, and, by estimating the ratio of leg to whole body, the result for the whole body in twenty-four hours equalled 2,376 k-units of heat given off. The same experimentation with cases of relapsing fever and rheumatism showed an increase of 70% to 75% in the heat given off. These experiments are still inaccurate because the lungs and loss by evaporation are not accounted for, but they are valuable because they demonstrate an increased heat-loss in fever, and necessarily, a greater heat-formation. One or two interesting conclusions were obtained. He found that the greatest loss took place during sweat-

ing; also, that the loss was increased both when the temperature was rising and falling; and finally, that the surface temperature varied independently of the rectal temperature. We must conclude, then, that we have a greater heat-production in fever, and that the function of heat-loss is very variable being greatest during diaphoresis.

What was desired was a series of accurate calorimetric measurements for the whole body. These were furnished by Dr. H. C. Wood.¹⁰ The experiments were conducted for years, and, on account of their elaborateness and accuracy, are of great value. His calorimeter contained the whole body of an animal. The principle was similar to Leyden's and Senator's, but all sources of error were eliminated as far as possible. The inspired and expired air were carefully measured, analyzed, and the heat-value noted. The CO₂ and urea were carefully measured, and errors due to the influence of temperature and barometric pressure of surrounding atmosphere were calculated. He found, as Leyden had done, an undoubted increase of heat-dissipation in fever. How does this take place? If the heat is chiefly produced in the muscles, it must find some means of reaching the surface, and this must be largely accomplished by the circulation, the greatest cooling taking place while the blood is passing through the capillaries of the skin. The more dilated these are, the slower the blood-current flows, and the more rapidly cooling takes place. Now it is well known that the vascular system is under the control of that portion of the nervous system called the vaso-motor system [v. m. system]. This has been demonstrated by Dittmar, Owsjannikow, and Heidenhain,¹¹ and the v.-m. centre has been localized in the medulla oblongata. Stimulation of this centre will cause contraction of arterioles, and so less heat is given off; paralysis will cause dilatation and a greater heat-loss. Evidently, heat-loss must be under the control of the nervous system. To demonstrate this, Wood cut the spinal cord of an animal below the medulla, and placed him in the calorimeter. He found that there was increased heat-loss and a fall of temperature, and, at the same time, there was diminished heat-production in the tissues removed from their nerve control. The fact of greater heat-loss after section of the cord was noted as long ago as 1811 by Brodie,¹² who showed, in addition, that a rabbit with the cord cut cooled faster than a dead rabbit under like conditions. M. Henri Parinaud,¹³ in some careful experiments, showed that after section of the cord the temperature fell progressively 1.5° in thirty hours, the temperature of the room being 67° F. The fall was more rapid, the lower the external temperature, and was lower in the paralyzed than in the non-paralyzed parts. Care was taken not to affect the respiration in these experiments. We are thus led to the conclusion that the fall of temperature is due to paralysis of the v. m. nerves by the section of the cord, and the resulting dilatation of the vessels of the skin. *Per contra* irritation of the v. m. centre or its nerves would cause spasm and retention of heat, with a rise of temperature. Both of these conditions are exemplified in fever. In the rigor with a cold, pale skin, you have contraction of arterioles and retention of heat; this

rapidly gives way to the hot, flushed skin, with increased heat-loss. If we look briefly at the respiration, we shall see that here, too, we get a greater or less heat-loss dependent roughly on the rapidity of the process, and that this is under the control of a nervous mechanism comparable to the v. m. system. It is evident, then, that heat-loss in the body is almost completely under the control of the nervous system, chiefly the v. m. system.

Now let us look at heat-formation. The most common illustration is the process of combustion, the union of carbon and oxygen to form CO₂ in a common coal-fire. Naturally, a similar process suggested itself as taking place in the body. We breathe in O₂, and take in C with our food, and we excrete CO₂ by the lungs; the ashes appear as urea in the urine. We must not forget, however, that the process is a complex one, and has to deal with complex organic compounds in going through constructive and retrograde metamorphosis. If we consider heat-formation from the standpoint of combustion, we get the following results: According to Professor Frankland's tables, we can estimate accurately the heat-producing capacity of different articles of food. One gramme of albumen yields 4.998 k-units of heat, and can produce $\frac{1}{3}$ gramme of urea. Now this latter, when given off from the body, still can produce .735 k-units heat; therefore, we must subtract the latter from 4.998 to get the amount of heat one gramme of albumen can furnish to the body. A healthy man on fever diet (inanition) excretes 17.5 grammes urea in twenty-four hours. To do this he requires 52.5 grammes albumen (estimated by the nitrogen in the two), and this can furnish 229 k-units of heat in complete combustion.¹⁴ Again, the same man will excrete 528 grammes CO₂ in twenty-four hours. His 52.5 grammes albumen, which he has taken to form his urea, will furnish 27 grammes of carbon, 3 of which go out as urea, while the remaining 24 are given off by the lungs. If we subtract this 24 grammes from the total amount of carbon given off by lungs in twenty-four hours (144 grammes), we have left 119+ grammes carbon not accounted for by the albumen eaten. This surplus carbon must come from the fat of the body, and would require 156 grammes fat to produce it.

This amount of fat can yield 1,419 k-units of heat. Add to this the 229 k-units derived from the albumen eaten, and we get 1,648 k-units as the total heat produced by a healthy man on fever diet. By the same calculation, we can estimate the heat-production of a man on full diet (Health), and of a man with fever (Fever) for twenty-four hours. The results give:

Inanition equals	1648 k-units.
Health equals	2118 "
Fever equals	2373 "
Heat-loss (estimated) equals	2276 "

"Health" is not on a full diet, but on a "balance" diet; that is, enough food to preserve the weight equilibrium. On the average diet, the heat capacity would exceed 2,118 k-units, and would probably equal 2,373 k-units. Thus we see that a man with fever and on fever diet can produce more heat than a healthy man on the same diet, but no more than a healthy man on a full diet. These results are doubtless not conclusive, but are interesting, particularly in

comparison with Leyden's heat-loss for twenty-four hours.

In our calculation, a certain portion of the heat was shown to come from the tissues of the body; what are the tissues consumed in fever? The albumen of the body is in two forms, circulating and tissue albumen. The former is rich in sodium, the latter in potassium. Salkowski¹⁶ has shown that in fever the excretion of potassium is increased. Therefore this and the increased urea must come from the consumption of the organized tissues (including the blood corpuscles, but not the liquor sanguinis). The excretion of the sodium is diminished, but is greatly increased after the fever is ended. Wood¹⁷ says that in his experiments there was a marked increase of heat-production after the ingestion of food, and that it must have come from the circulating albumen. But as there is increased heat-production in starvation with fever, in the flowering of plants, and in muscular exercise, it must at times come from the tissue-albumen. There are thus two sources of heat in the body, and the fact that the food is one of these is of direct practical importance in connection with the question of feeding fever patients. "Graves fed fevers."

We have seen how we may get an increased heat-production in fever, and calorimetrical tests prove that this increase actually does occur. Dr. Wood¹⁷ has shown that by measure there is more heat formed in fever than in health under like conditions and sometimes even more than in health with a full diet. It is probable that there is a difference in heat-production in different patients and in different fevers. But he developed a most interesting fact. In his experiments on heat-loss after section of the spinal cord he found that he sometimes got a rise of temperature if the surrounding medium was warm (90° F.), or the animal specially vigorous. As his animal was losing more heat, he concluded that some agency must be at work to increase heat-formation sufficiently to overbalance the loss. If he could cut the cord high enough to leave the v. m. system intact, he could determine whether the nervous system had any control over heat production. With great care he made such a section at the junction of the medulla with the pons, and got a following rise of temperature. He proved the v. m. system to be still intact by irritating a sensitive nerve after section of the vagus, and getting a spasm of the vessels and a rise of blood-pressure. With the increased heat-production there was increased loss, but the former prevailed, and the temperature rose continuously for twenty-four hours while the animal lived. If there is a force removed by his section above the medulla, what and where is it? Euleuberg and Landois¹⁸ demonstrated that, by destroying a certain portion of the "first cerebral convolution posterior to the sulcus cruciatus," they got a rise of temperature on the opposite side of the body, and on irritating this spot they got a fall. Hirtzig¹⁹ and Wood have confirmed this. Heidenhain²⁰ furnished additional evidence of the existence of a nerve-centre controlling heat by showing that strong irritation of a sensitive nerve was followed by a fall of temperature though the blood-supply was cut off: and we have already seen that

irritation of a motor nerve will cause a rise under like conditions. Mantigazza and Wood both confirmed Heidenhain's conclusion, and the latter showed in addition that there was often a preliminary rise due to muscular spasm and v. m. spasm, that gave way quickly to a permanent fall. If this result is due to the influence of your irritation on a heat-centre, and you can cut its nerve, irritation should no longer cause a fall of temperature. Experiment showed this to be true. It seems highly probable then that there is a nerve-centre above the medulla that controls heat-formation, and that it is inhibitory in character. Aronson and Sachs²¹ have been able to cause a rise of temperature and an increase of the secretion of CO₂ and urea by passing a needle into a rabbit's brain on the "medial side of the corpus striatum."

The rabbit ran about as usual and no portion of the brain was injured. By a mild current of electricity they could produce fever *at will* for short or long periods. If these experiments are verified they will undoubtedly show the existence of a nerve-centre that stimulates heat-formation, thus making the nervous control of heat-production a double mechanism similar to that controlling heat-loss.

Is there any clinical evidence for the existence of a heat-centre? I must refer you for a careful and suggestive paper on this subject to one by Hale White.²² He cites many cases, and concludes as follows: Many tumors of the brain, pons, medulla and cord cause a rise of temperature, and such tumors are situated in just such a position that they would impinge on the supposed inhibitory centre or the fibres running from it. *Per contra*, other tumors do not cause a rise of temperature, although you would expect them to do so if their action was due to anything but pressure on a definite portion of the nervous system. The same is true of hæmorrhages and embolism. Wood has reported a case of hæmorrhage into the pons (where the heat fibres are supposed to run) where the temperature of the paralyzed side was higher for months than the other side. Certain nervous hyperpyrexias can be explained on no other ground, and hysterical pyrexia adds weight to the hypothesis. Parinaud²³ reports a case of epilepsy where the temperature went on rising after the severe muscular spasms had ceased, and was highest (109° F.), fifteen minutes after death. Finally, many neuroses, locomotor ataxia, insular sclerosis, injuries to the brain and cord that do not give rise to inflammation, still cause high temperature, and go far in confirming the belief that the nervous system controls heat-formation.

Have we reason by analogy for the existence of a heat centre? The great advances made in cerebral localization throw light upon this question. We know where the nerve centres for sight, hearing, speech and taste; for mastication and deglutition; for respiration, the heart, and v.-m.-system, are all situated. Again we know that the nervous system controls nutritive processes, as bedsores, herpes zoster, secretion of milk and many others. Now, if the nervous systems controls these processes (and the list is constantly growing), why should it not control a function so essential to the economy as heat-formation?

We are now in a position to consider some of the thermic phenomena of the organism. If a cold-blooded animal with a temperature but little above that of the

²⁴ Op. cit.

surrounding air is subjected to cold, he suffers a fall of temperature corresponding to the outside change, and the amount of CO_2 and urea excreted is diminished. This may go on till the freezing point is reached with snails and gold-fish, and yet recovery may take place on again warming them up, with an increase of CO_2 and urea. But expose a warm-blooded animal to cold and you get an increased heat-formation with more CO_2 and urea excreted. More heat is also given off, but there is no change of body temperature. Now suspend the action of the nervous system with urari poison in the latter class, and they behave just like cold-blooded animals. Evidently physical laws are not sufficient to explain these phenomena, and we must look to the nervous system for an explanation of these heat changes. How are they accomplished? It is now known that there is a temperature sense, that there are nerves terminating in the skin that are acted on by heat and cold. Pflüger²³ observed that a patient, who was paralyzed as to his tactile sensation, could still distinguish between heat and cold. By analogy, stimuli affecting these nerves should by the law of reflex action affect the heat centre, and produce corresponding changes in temperature to meet the requirements; but this is only possible supposing nerve centres to govern the heat processes. Again, the temperature of children is much more susceptible of variations, both in health and in disease, than that of an adult, and, what is equally true, they have less control over their reflex action, that is, the nervous system is less stable.

One of the most constant and significant of fever phenomena is high temperature. What is it, and what its meaning? I will first state what it is not by a seeming paradox. *Temperature, as indicated by the clinical thermometer, is not alone a correct guide of the fever process.* In one of Wood's experiments the respiration was stopped, and thus no oxygen supplied for combustion, but the temperature continued rising, owing to v. m. spasm and retention of heat; this is also seen in the post-mortem rise of temperature. Consequently, you may have a high temperature, though the fever process is not very active. The reverse is also true, and you may have a low temperature due to greater heat-loss by profuse sweating or paralysis of v. m. system, though the consumption of tissue is still going on with unabated energy. I do not wish you to understand me as saying that, in general, a high temperature does not coexist with rapid tissue-change—it probably does—but it is not an essential coexistence, and is subject to great variation. Therefore, we must not go to a patient, and, because we find a relatively low temperature, conclude that the processes that are undermining life are not very active; the contrary may be true. We must look to other evidences of tissue-metamorphosis in the amount of urea and CO_2 eliminated [the amount and specific gravity of the urine, and the rapidity of respiration, would serve as bedside-tests], and in the condition of the skin, and particularly the nervous system, in order to satisfy ourselves of the activity of the fever process, and not depend too implicitly on our thermometer. Otherwise we may lose our patients unexpectedly, and find others recovering who were apparently the sickest. This is illustrated in the case of many children's ailments, where a sudden high temperature evidently does not indicate extensive tissue-consumption, for we

see them recovering with comparatively little effect on nutrition. What, then, is temperature? It must evidently depend upon the play between heat-loss and heat-formation. Given increased heat-formation, you will get a rise of temperature whether the heat-loss is diminished or stationary, or increased—provided the increased loss is not enough to compensate for the increased formation. Again given a diminished heat-loss, and you will get a rise of temperature under any condition, save a great diminution in heat-production, and even then the high temperature may last for some time; for example, after death. If, during fever with heat-formation and heat-loss, one increases and the other decreases at the same time, you may get, in one case, a rapidly rising temperature; in the other, a corresponding fall.

In looking at the relation of the nervous system to the fever process, we have seen that heat-loss and heat-formation are probably each under the control of a double-acting mechanism, motor and inhibitory, and this is rendered the more probable when we consider the double control of the heart and respiration. But further than this, it seems evident that there must be somewhere among our nerve-centres a power that co-ordinates these two functions. When we consider our two variable factors (heat-formation and heat-loss) under such control that in health they give a constant temperature, whether a person lives in Iceland or in India; when we note that in fever, with all the disturbance caused by influences from without and within, the two factors are still under control, and seeking to find equilibrium, we must conclude that some force directs their separate fluctuations so as to bring them into harmony. What it is we do not know, any more than we know what power co-ordinates all the wonderful muscular movements of our body, but only that it must reside in the higher nerve-centres.

(To be continued.)

HYPERTROPHY OF THE GLANDULAR TISSUE AT THE BASE OF THE TONGUE, WITH REPORT OF CASES.¹

BY JOHN W. FARLOW, M.D.

THE existence and importance of the glandular tissue at the base of the tongue has received but little attention hitherto. Anatomists and microscopists have differed in regard to its character and extent, and clinically it has been almost overlooked. In the ordinary examination of the throat with the tongue-depressor, the base of the tongue is usually below the line of vision. When looking at the larynx with the laryngeal mirror, the epiglottis, arytenoids and vocal cords claim so much attention and are so often the seat of disease, that the back of the tongue is forgotten. In many people the tongue is so arched, thick and resisting that it is not easy to see its base. But, in view of the possibility of finding some morbid condition in this place, it is advisable, as a routine practice, to depress the base of the tongue so as to get as complete a view as possible of its entire length, even to its junction with the epiglottis. With the laryngeal mirror, a better view of the glossoepiglottic space can generally be obtained by holding the mirror not as in looking at the larynx but farther forward and higher in the

²³ Arch. für die Gesamte Phys. 1878.

¹ Read before the Suffolk District Medical Society, Section for Clinical Medicine, Pathology and Hygiene, December 14, 1887.

mouth. The anterior surface of the epiglottis and its relation to the base of the tongue should be carefully scrutinized.

Treatises on Diseases of the Throat have, thus far, had practically nothing to say on the subject, and so recent a writer as Butler, on 'Diseases of the Tongue,' makes no mention of the condition.

Glandular tissue, to a greater or less extent, is nominally present in most individuals after the age of puberty, but before that it is but slightly developed. But a degree of enlargement of this tissue sufficient to be considered pathological and give rise to symptoms calling for its removal, seems not to be as common as we should expect when we consider how common hypertrophic changes are in the throat, especially in our changeable New England climate. My attention was first called to this subject by an article by Dr. H. Holbrook Curtis in the *New York Medical Record* for 1884. Since then I have examined more carefully for the condition he described, and although a very large number of throat patients have been under my observation in the throat clinic of the Boston Dispensary, I have been surprised to find how few cases really called for treatment, not more than five or six, I should say.

According to Swain,² who has written the most extended account of this condition, the hypertrophy is a simple, chronic inflammation of the follicular glands with hyperplasia. I have also seen instances in which this tissue swelled more acutely, adding to the severity of an ordinary pharyngitis and exciting to violent expulsive efforts to cough it out.

These follicles are sometimes uniformly enlarged and arranged with fair symmetry, or they may take the form of one or more large masses on either side of the tongue, and in all my cases there had been a reddish, boggy, nearly oedematous look. Often the opening of the gland with a little secretion in its mouth can be seen.

Not only the amount and seat of the hypertrophy should be determined, but also its relation to the epiglottis and the peculiar character of the latter. If the glosso-epiglottic space is naturally small and the epiglottis very flexible, its tip is more likely to be caught in the glandular mass, or be pressed on by it, than where the epiglottis is firmer and more erect, and the glosso-epiglottic region larger, even if the hypertrophy is no more. So that it is important to determine whether the epiglottis in its various movements and positions is really pressed against or entangled in the glands.

My most marked case was in a young lady about thirty, seen in May, 1886. She had always had a sensitive throat, and been subject to a distressing cough, although, in other respects, she was in excellent health. She had a very good voice and took lessons and sang a great deal. About a year before I first saw her she began to complain of a tickling in the throat and to feel as if some foreign body were there. Her cough became more violent in her evident efforts to rid herself of the source of her discomfort, and this often caused vomiting. Her voice became thick, husky and easily fatigued, and she was obliged to give up her singing. I found the whole fauces, pharynx and larynx very red, but what attracted my attention most forcibly was the complete filling up of the glosso-epiglottic space by hypertrophied tissue. In the me-

dian line the follicles were considerably enlarged but of uniform size. On the sides the hypertrophy took the form of a large rounded mass which was in contact with the epiglottis, the mass on the left being larger. Cocaine applied directly to these growths removed the feeling of a foreign body and the coughing stopped. I applied glacial acetic acid to the masses on the sides and tincture of iodine to the smaller growths in the centre. After several applications the hypertrophy had very much diminished and all the symptoms disappeared. I directed astringent gargles to be used for some time.

The patient has since left Boston, but a letter recently received from her tells me that she has been well ever since. A throat specialist, who has lately examined her throat, reports no return of the hypertrophy.

As an example of the more uniform enlargement of the follicles I will simply refer to one other case, a young woman twenty-four years old, who had been supposed to have laryngitis. She had the feeling as if a foreign body in the throat and a violent, expulsive cough with weak voice. The follicles were numerous and large, but of a uniform size, (there being no large masses as in the first case), and pressed against the epiglottis. Application of tincture iodine and the use of astringent gargles were sufficient to cause all her symptoms to disappear.

My other cases have been quite similar to the one last cited, and have all been women not far from thirty years old, and in good health. This may be chance, but, from the difference in their nervous sensibilities, of course, a much smaller degree of hypertrophy of these follicles would be sufficient to cause symptoms demanding treatment in a woman than in a man. It has been suggested that many cases of globus hystericus might be due to pressure from these follicles. My own observations are not sufficient to warrant my forming a definite opinion, but the symptoms in my cases were not at all such as are usually called globus hystericus. I hope this will be particularly inquired into by those who have many hysterical women under their care.

As regards etiology my cases gave me no information. None of them presented other than the history of occasional or frequent colds and coughs. As all were in good health it would seem to have no connection, either as cause or effect, with serious disease. Unlike hypertrophy at the vault of the pharynx it cannot do any great amount of damage without causing cough or some symptom marked enough to impel the patient to seek medical advice.

The symptoms caused are irritation in the throat and the feeling of a foreign body, cough violent and expulsive, huskiness, fatigue in speaking and singing, and weakness of voice. Sometimes the epiglottis, being imprisoned in the glandular mass has caused more active feelings of distress, such as laryngeal spasm, relieved by freeing the epiglottis. Such instances have been recorded by Rice,³ Betz,⁴ and others.

The treatment seems to be very satisfactory and is like that employed for similar hypertrophies in other locations. Where the follicles are not in the form of large masses, applications of tincture of iodine cause a diminution in the size. Swain² used with good result

Lugol's solution, liquor iodinii compositus. Where large masses are present applications of caustic, glacial acetic or chromic acids, Vienna paste or the galvanocautery bring about a much speedier disappearance of the growths. A bent wire applicator can be used with the aid of the laryngeal mirror or, in some cases, where the tongue can be completely depressed, no mirror need be used. Later, astrigent gargles are of benefit. Cocaine is an aid in the diagnosis and also of service in the treatment.

NOTE ON AN ANOMALOUS ARRANGEMENT OF THE LARGE VEINS OF THE NECK.¹

BY J. G. FINKHAM, M.D., LYNN, MASS.

IN making an examination of the body of the young colored woman who was recently killed in Lynn, by a razor wound of the neck, an anomalous arrangement of the large veins of this region was discovered, which it seems to me worth the while to describe and place upon record. The cut began one inch in front of the angle of the jaw on the left side, and extended obliquely downwards and forwards a distance of two inches, to the top of the thyroid cartilage, thence parallel to the lower jaw on the right side, a distance of two-and-a-half inches. The structures divided were the skin, the subcutaneous cervical muscle, the superficial layer of the cervical fascia, and the sterno-hyoid muscles. The thyro-hyoid muscle of the right side and the thyroid cartilage were cut into. At the bottom of the wound on the right side, and far out, was seen a large vein partially severed and still bleeding. From its position, this was at first supposed to be the external jugular vein; but when followed upwards with a probe it was found to divide into two main branches, one of which passed upwards and inwards to the region of the jugular foramen, and the other upwards and outwards to the front of the ear. Below, the main vein was found to dip beneath the sterno-cleido-mastoid muscle, and to join the subclavian, forming with it the innominate of that side. Further dissection revealed the carotid in its sheath with the pneumogastric nerve, in their usual positions, but with no vein accompanying them. It was therefore concluded that the internal jugular vein, in descending from its point of origin, had abandoned its place by the side of the internal carotid, and turning outwards towards the surface, had joined the external jugular to form a common jugular, which from this point pursued a course downwards midway between the course of the external and that of the internal jugular, until it joined the subclavian. This common jugular, although loosely invested with fibres from the cervical fascia, was entirely outside and above the sheath of the carotid. In order to make sure of my conclusions, I followed the bloodvessels upwards from the *vena cava descendens*, and laying them open verified every point. The arrangement on the left side was found to be the same as on the right, except that the vessel was smaller. As the cut was higher in the neck at this point it struck the vein in its most superficial position, and completely severed it. Had it not been for this unusual arrangement of the large veins, it is possible that the cut, severing as it would have done, only the external jugulars, might not have

caused death, or at any rate might have proved less speedily fatal. As it was, death occurred from hemorrhage in about twenty minutes, as nearly as could be ascertained, after the infliction of the wound.

Clinical Memoranda.

AN EPIDEMIC OF MEASLES.¹

BY W. D. HODGES, M.D.

AN unusual opportunity to observe an epidemic of measles at a charitable institution, from its inception to its end, is my apology for bringing this subject before the Section.

On January 27th the institution contained sixty-five children, between the ages of one and sixteen years—fortunately, a much smaller number than usual. On that day, a child six years old was admitted, and, as it had a severe cold, was sent at once to the sick ward. Twenty-four hours later an eruption appeared, which proved to be measles; and it was subsequently learned that the child had been exposed to this disease. On the same day that this child developed measles, three children were discharged from the ward in which he was put. Nine days after the discharge of one, and eleven days after the discharge of the two others, they developed measles, and had also conveyed the contagion to 14 other children, who were admitted to the hospital on the following day. Sixteen more children were taken sick on the 22d and 23d days after the breaking out of the *first case*; that is, eleven and twelve days after the development of the *first set* of cases. During the next seven days, that is, between the 29th and 26th days, 12 more children developed the disease.

Of the remaining 20 children in the institution who escaped measles, 10 were sent away: 8 had already had measles before they were inmates. In two instances, no definite information could be obtained.

The epidemic was confined to 45 children, 39 of whom were between the ages of four and seven years; and its fatality was represented by five deaths—one of whom had capillary bronchitis, and the four others diphtheria.

Examination of the throat in 30 cases showed a varying amount of congestion of the pharynx, palate, and tonsils, with, sometimes, red papules. Three cases with very marked congestion were followed, in twenty-four hours, by diphtheria, two of which were fatal.

The eruption was at its height on the fifth and sixth days, and lasted from twelve to fourteen days. In eight cases it did not disappear for over three weeks, and this group included the four oldest children, aged, respectively, nine, ten, eleven and nineteen (a servant).

It is interesting to note that two of these cases of long duration of the eruption were complicated with capillary bronchitis, one with pneumonia, and one with diphtheria. One of the children with capillary bronchitis died.

Desquamation was noticed in a large number of cases—probably more than half—in a few of which large pieces of cuticle were thrown off.

The enlargement of the glands in the neck was

¹ Read before the Massachusetts Medico-Legal Society, February 2, 1887.

² Read before the Section for Clinical Medicine, Pathology, and Hygiene of the Suffolk District Medical Society, December 14, 1887.

most marked in those cases that had considerable congestion of the fauces.

Aphthæ upon the lips and tongue were very severe in nine cases.

There were 25 cases of otitis, most of which were detected during the first week, the children crying without apparent cause, and raising their hands to their ears.

There was one case of convulsions, which came on three days before the eruption. This child made a rapid recovery.

Epistaxis and diarrhœa were of frequent occurrence, but never a cause for anxiety.

Conjunctivitis, with intolerance of the light, was present in most of the cases, and was treated with a solution of borax, glycerine, and water.

The highest temperature noted was 106°, in a case complicated with capillary bronchitis, which proved fatal. The temperature usually fell slowly after the eruption had reached its point of greatest development. It was generally subnormal during convalescence.

The treatment consisted chiefly in maintaining cleanliness and regulating the diet.

A SECOND ATTACK OF MEASLES AFTER A SHORT INTERVAL.

BY J. A. JEFFRIES, M.D., OF PHILADELPHIA.

THE cases of measles described below seem to me worthy of note, owing to the perfect health enjoyed during a short interval between the two attacks. It hardly seems logical to call the second attack a relapse, yet, as a case of second attack, the interval is very short. Of the identity of the two attacks there can be no reasonable doubt.

J. C., four years, healthy child, began to sicken on the 4th of June "with cough and eyes." First seen on the 6th, when the patient had a rash on the face, chest, and back. The rash was red, of the color most common during the last epidemic of measles, slightly itching, elevated, distinct, the spots varying in size from a sixteenth to a quarter of an inch in diameter, and roughly circular in form. Legs free; rash not stippled or in the form of a blush. Fæuces slightly reddened, lungs resonant, full of large, moist râles, soft cough, no diarrhœa; pulse 80, morning temperature 98.4°, respiration 22. On the morning of the 7th the rash was more developed on the body: pulse 94, temperature 99°, respiration 34. The rash rapidly vanished, did not scale, and by the 13th of June the patient showed no sign of disease.

During the next four weeks, I saw the child frequently playing about the house.

On July 20th he suddenly sickened again with "cough and red eyes," and, on visiting him on the morning of the 22d, the following condition was found: Eyes, catarrhal conjunctivitis; face with a red, distinct, papular rash over malar bones, spots from a sixteenth to a quarter of an inch in diameter; light, soft cough, large, moist râles, slight congestion of fauces; temperature 99°, pulse 100. On the 23d the rash had spread over the body, was patchy, and the cough increased. The next day, saw a change for the better, and the child rapidly returned to health, though distressed by a crop of little blisters on the 26th, apparently due to too much iodide of potash.

Nine days later, May McC., one year, living in the same house, came down with a mild, but distinct attack of measles.

"German" measles I have seen in Europe, and feel competent to make a differential diagnosis.

New Instruments.

A MODIFICATION OF THE "PERINEUM DISTENDER" TO AVOID ITS INTERFERENCE WITH RESPIRATION.¹

BY W. W. KEEN, M.D., PHILADELPHIA.

IN the frequent use of the "Perineal Distender" I have found the strap which passes under the nape of the neck very objectionable. This strap flexes the legs, and supports their weight. While doing so the weight of the legs pulls the head and neck strongly forward, and thus often seriously embarrasses the respiration.

To avoid this, I have had the wooden shoulder-piece of the old Day's apparatus for fractures of the clavicle slightly shortened, and find it answers admirably. Under its loops, over each shoulder, two straps are passed with a buckle turned wrong side foremost at one end. The other free end, after passing through this buckle in the armpit, then is buckled to the cross-piece between the legs. By this means the pressure is brought on the shoulders instead of the neck, and respiration is entirely unimpeded.

I have also had two straps attached at right angles to the straps for the legs. By this means the leg-straps can be secured above the calf as usual or at the ankle. In this last position the new straps, by passing under the foot-soles, more completely flex the legs and get the feet out of the way of the operator.

—The *Dietetic Gazette* points out that all the heavy work of the world is not done by men who eat meat. The Roman soldiers, who built such wonderful roads and carried a weight of armor and luggage that would crush the average farm-hand, lived on coarse brown bread and sour wine. They were temperate in diet and regular in exercise. The Spanish peasant works every day and dances half the night, yet eats only his black bread, onion and watermelon. The Smyrna porter eats only a little fruit and some olives yet he walks off with his load of a hundred pounds. The coolie, fed on rice, is more active, and can endure more than the negro fed on fat meat.

ALBERT N. BLOMGETT, M.D., SECRETARY.

DECEMBER 14, 1887.

The meeting was called to order at 8.00 p. m., by the chairman, Dr. A. L. MASON, who after a few introductory remarks, called for the

REPORT OF THE COMMITTEE ON MILK.

appointed June 7, 1887, to take into consideration what further action the section could properly undertake in regard to the milk-supply of Boston. The report as presented was published in full in the daily newspapers (December 19, 1887.)¹

Dr. JOHN W. FARLOW read a paper on

HYPERTROPHY OF THE BASE OF THE TONGUE, WITH REPORT OF CASES.²

Dr. S. W. LANGMAID said: My observation is a good deal like Dr. Farlow's. I remember one example of the disease where a young lady was perfectly unaware that there was anything out of the way, but her music teacher had looked into her throat, and seeing something wrong sent her to me. There was a growth half as large as a filbert, on the back of the tongue, the nature of which at first puzzled me. But I soon found out what it was when I punctured it. It was very vascular, and by successive examinations I made up my mind that it was adenoid tissue. I don't think that it gave the young lady any discomfort, but the teacher, because the tone of her voice did not please her, had the curiosity to look into her throat, and discovered the tumor. I must say that I have never known much trouble to be caused by it.

I don't recall a case of such extensive hypertrophy as Dr. Farlow speaks of. That seems to be an extreme one. It is not at all strange, it seems to me, that there should be hypertrophy there very frequently, because the condition is about the same as we get in the tonsils and the region would naturally participate in any inflammation of the pharynx or fauces. The wonder is rather that we see it so seldom. Perhaps it is that we don't look for it, as Dr. Farlow suggests. It seems to me that our attention would be called to it if the growths were very prominent, or gave rise to much disturbance.

I have sometimes thought in the lesser cases, where the hypertrophy was not very great, that the original cause was in the digestive organs, and that has especially, I think, been shown in the diminution of the growth by the treatment of some dyspeptic trouble that the patient might have. Local applications of iodine I suppose are always made if there is much enlargement. Then, as I said, if the attention is directed to the digestive organs, very frequently I think the trouble will be found there.

Only this afternoon I saw a case where there was much hypertrophy, and where there was on the sides of the tongue, nearly at the base on both sides, an irritated spot. The patient came to me on account of the irritation, and examining it, I found a kind of tes-

sellated looking surface, made up of small glands, not the circumvallate papillae, but other glands, and they were extremely sensitive. That has occurred in my practice a good many times.

It has given rise in the mind of the patient to the fear that a malignant growth was forming. The irritation is generally, I think, on both sides of the tongue. That is a fortunate thing as you can assure the patient that it is not a malignant growth.

And then if you examine into the case you will almost always find that there is some digestive disturbance. That taken care of, the irritation disappears, and the enlarged follicles diminish in size. I agree with what Dr. Farlow has said in regard to the few observations that have been made. Yet it has been well-known. The very oldest writers speak of these hypertrophies. The old anatomists speak of them, but draw no conclusions, and say nothing with respect to their clinical importance. I remember the remark that some of the cases of globus hystericus might be referable to them, but I have had no reason to think in my cases that there has been anything of the kind. It seems to me that Dr. Farlow's paper is a very timely one, to call attention to the subject, and perhaps we shall know more about it than we do now.

Dr. T. A. DEBLOIS said: I think we have all noticed the increase in the number of those cases since the death of General Grant. A great many women imagined that they had cancer, and in that connection I have been consulted a good many times. Last year there was a case at the City Hospital in one of the nurses, who had quite a large growth, and she was fully possessed of the idea that she was developing a cancer. She had a good deal of pain in the growth, too, more than you would be led to imagine from the appearance. I found that besides the ordinary iodine applications, the syrup of hydropic acid seemed to have a very beneficial effect. The glands diminished in size, and the pain passed off in the course of a week or so. She had a good many applications. They have never returned so far as I know. Two months ago I had a case of a similar kind where the pain was considerable. Here, also, it seems as if the syrup of hydropic acid had a good effect.

There was a case last week rather different from any described by Dr. Farlow, in which, upon the base of the tongue, and perfectly symmetrical, were two patches which appeared to be enlarged papillae. They were very much hypertrophied and were very hard, feeling to the probe almost like the calcareous degeneration which takes place in the tonsils sometimes. These papillae overlapped as the leaves of a flower. They were very tough. You could get very little on scraping them with a curette. I scraped until the tongue bled all around, but got very small particles of this off. I managed finally to wrench off some pieces with the forceps. They did not change at all under the applications of glacial acetic acid or constitutional treatment. The patient disappeared. It was the first of the kind that I have seen. Dr. Langmaid says he has seen two or three of the kind, but I never saw anything before like it.

Dr. W. D. HODGES then read a paper on

AN EPIDEMIC OF MEASLES.³

Dr. S. H. DURGIN said: I have been asked to say something on this paper. I did not know what the

¹ Boston Herald.

² See page 116 of the Journal.

³ See page 118 of the Journal.

points would be. I presumed it would be something about the nature of official interference in this disease, as in some of the other contagious diseases, and perhaps it will be worth speaking about. So far as the epidemic is concerned, I don't know that there is anything more than the complement we ought to pay Dr. Hodges for the wise care and the points brought out in the case. It gives additional evidence in regard to the time when the disease may convey itself to others. It is oftentimes a question with physicians as to just when the point of danger begins in most of our contagious or eruptive diseases. I am very frequently asked the question whether the other children ought to be taken away at one time or another, and particularly as to when exposure might be dangerous.

I think that in these cases reported, the evidence seems very clear that the point of danger reached by these first cases was very early. And I think, if I remember correctly, that it was very quick for the eruption to appear. In small-pox the question is very frequently asked whether there is danger of contracting the disease before the eruption is clearly defined. It has been my experience that the danger begins certainly as early as any kind of an appearance of an eruption is shown. I think the same may be said of scarlet fever; and it certainly seems to be true of measles.

In regard to the care of measles, it has always seemed to me, and particularly since my connection with the health office, that the same care in isolation and in disinfection should obtain as is called for in small-pox, in scarlet fever, and in diphtheria. It is to be regretted, I think, that among people in general, and I am even more sorry to say, among physicians largely, the feeling is that this disease does not amount to much, and the children will have it anyway, and we might just as well cease to interfere. I cannot think so, particularly when we find so many deaths yearly from this disease. It is just as much loss to your family when the child dies of measles as when he dies from diphtheria or the small-pox, and yet in the community, if your child dies of measles, little is thought of it. If it dies from small-pox or diphtheria or even typhoid fever, there is a great deal said about it, and there is great fear lest some one else will die of the same disease. Now I cannot see why this feeling should not exist in regard to measles. I don't think that it is absolutely necessary that the child in childhood should have measles. Neither do I think so of scarlet fever.

I don't know that in measles the susceptibility diminishes after childhood, in the same way that it does evidently in scarlet fever, and yet it strikes me that we should keep our children from measles as well as from the other diseases.

And then in regard to official interference. It has been a question with me, or rather it has been a question with the Board of Health in our city, as to whether we should insist upon isolation and disinfection.

If we did so it would increase the work immensely, as there are a great many cases. I think there are a great many more cases than there would be if official interference obtained. It would add very greatly to the work, and the feeling is as a general thing that we had better not interfere with the measles. I would like very much to have an expression of the feeling of the section. I think it would govern me

largely. I think it would aid me very much in my conclusions.

I feel personally as if an interference ought to be made. This afternoon I took occasion to consult the records, thinking perhaps you might be interested to know how many deaths have occurred from measles in the last few years. I went back to 1863, and found 1,117 deaths in these twenty-three years lacking a month. This gives an average of forty-eight deaths per year. Supposing we had forty-eight deaths a year from small-pox, as we used to have. You would criticise me.

In 1883 the Board sent out an order that the cases should be reported; and sent a circular to the parents and the School Board, advising that the children coming from families where there was measles should be taken out of school. In these three and a half years there have been 5,354 cases of measles reported. This is an average of over 1,500 cases per year. I have looked over the per cents, and have found that the per cent. of deaths to the total number of cases was: In 1884, 5.1%; in 1885, 5%; in 1886, 4.5%; in 1887, 5.2%, for the eleven months just past. That is, allowing that we get a report of all the cases, as we do of all the deaths, then the rate of mortality is about five per cent. Of course that is not a heavy per cent. for a contagious disease, but it presents a mortality ranging in sixty-five years from the smallest number, two, to the highest number which is one hundred and fifty-two. I thought these facts might be of interest to the profession, simply to show the number of deaths that are occurring, and the percentage of deaths to the number of cases. And as I said before, I would be very glad to have an expression of the opinion of the profession in regard to the desirability of interfering with the measles officially.

DR. BARNES said: I would like to know if Dr. Dargin has had experience with the effect of disinfection; if any influence is produced?

DR. DARGIN: We have not insisted upon it, although we advise it. We don't follow them up. So far as scarlet fever is concerned, I have had a large experience, with the best results.

DR. H. I. BOWDREN: Do I understand that any legal measures now are taken? May a person have measles and not do anything about it?

DR. DARGIN: Yes, they must report it. As soon as a case is reported we send a circular to the house, which gives general considerations as to the desirability of isolating the patient, and the general care to be used in preventing the spread of the disease and the consideration for disinfection when the case is over. And we offer to do the disinfecting if they desire it. We don't compel it, because the statute law does not include measles in the list of diseases where the persons are called upon to disinfect.

DR. JAMES AYER: Dr. Hodges' admirable paper shows that he had exceptional advantages, and used them well. He shows that there are dangers in measles, and it is proper to say at the outset to every family in which a case of measles occurs that there is great danger in underrating the importance of the disease. They might laugh at you, but you have done your duty if you say that the case should be isolated as far as possible. The danger lies not only in the disease itself, but the sequella. I think that every case should be reported, and that circulars should be sent to the homes in every case. In my

experience with the epidemics of measles, I have noticed that some other epidemic soon followed. I would like to ask about it.

DR. HODGES: There was no sickness after the measles had disappeared. The children were all moved, about three weeks after the epidemic to the country, where they remained all summer. While they were still in the city before they were moved to the country, they were all taken away from the home, and the house thoroughly fumigated. Then they were brought back to it. In three weeks time they were all sent to the country, where they stayed until the autumn. Just before their return this autumn, the building was again thoroughly cleansed and fumigated. There has not been any sickness there to speak of since the epidemic. There have been one or two cases of a trifling nature, but no epidemic, or any other disease of a contagious nature.

DR. E. G. CUTLER: I was greatly interested in hearing what Dr. Hodges had to say. I had an experience also in a public institution, taking in a class of patients quite like those that he speaks of. This happened several years ago. There were, I think, something like seventy-five or more persons in the house. They varied in age from about two and one-half and three up to fifteen or sixteen. Out of that number, first and last, there were forty-five who had the measles. The epidemic was a mild one; it was accompanied by very little fever, and there were none of the severe throat symptoms that the Dr. speaks of. Nor was there any patient who had trouble with the ear. The chief symptom was tremendous coughing, which was quite hard to control at first. The children were isolated. They lived in a house which was not connected with any other, and were kept in isolation for some time.

I could not make out whether all the people in the house who did not have the measles had had the disease before. But I took it for granted that all who did not have it before had it then. It certainly was the case that some of the individuals who were sick had had a disease which corresponds quite closely with measles, even if it was not that.

In these cases it was mild, and they were isolated merely as a precautionary measure. I forget how long the epidemic lasted, but it kept me trotting up there every day for a number of weeks. I thought then that if there had been a law like that which is enacted about scarlet-fever and small-pox, it would have been a good thing. I, for one, would be glad to see the Board of Health have the same power here as in other diseases.

DR. BOWDITCH: I hope the meeting will not close without our doing something about it. I think we ought to put it in the same list as the scarlet fever. I move that the sense of the meeting is that it should be placed under the care of sanitary officers, as other cases of disease.

DR. DURGIN: I would like to say for the information of the last two speakers, who perhaps think that the authority is not sufficient now, that the authority now is fully as great concerning measles as it is concerning small-pox. It is simply a question as to whether the Board of Health would be going beyond what would be regarded as prudent, in doing with these diseases as they do with the other contagious diseases; whether we would be going beyond the point of prudence in insisting upon disinfection. It

seems it kills five per cent. We ought to have the power of taking measures to prevent it.

DR. CUTLER: I would like to ask whether the Board of Health has not the right to take a small-pox patient from anywhere in the city and carry him away to a particular place, and detain him there until he is cured, and whether that same power is extended to these other diseases. I had supposed that it was only small-pox.

DR. DURGIN: We have the same right in all of these cases. Any one who we should decide has a disease dangerous to the public health we could carry to the hospital. The limitation on each of them is this: We can take them from any house except where, in private families, the attending physician and the Board of Health think that the patient is properly isolated there, or is so ill as to make it impracticable or dangerous to the health of the person to move him. In other cases the Board of Health has the legal right to take the patient away.

But here is the interesting part of the question. The Board of Health has a hospital for small-pox, and we can take all the patients who are likely to come in. But in no other disease have we any hospital under our charge or control in any way. The City Hospital has a little room for contagious diseases, wholly inadequate, and we advise patients to go occasionally, and occasionally get patients to go, but if we are to take hold of diseases like measles, and say that we will carry every one that needs care to a hospital, from defective houses and other places where the liability to spread is very great, we should get blocked in a very few days. But still there is much that we may do by insisting on isolation at home so far as it might be carried, and disinfection when the case is over.

DR. CUTLER: Disinfection by the Board of Health?

DR. DURGIN: Yes, sir.

DR. CUTLER: I should think that would be a very wise proceeding.

DR. AYER: I am perfectly aware that cases should be reported, but I don't think the sentiment of the profession is so strong in reporting them as in other cases. It is hard to carry out accurately without sentiment to back it. I would like to ask what proportion of cases Dr. Durgin thinks reaches him; if he supposes that he hears of one-half of them?

DR. DURGIN: That is a very hard question to answer. I fancy there are a great many cases that we don't hear from. There are some cases where no physician is called. They are diagnosed at home. The mother takes charge of measles frequently without calling a physician. In these cases, although the householders are responsible, if the notice is not sent in, yet they don't do it. There are a great many cases that I don't hear from, and these are the cases that spread the disease, as a light case will spread the disease much faster than many of them. No care is taken. The greatest freedom is used in going out and in.

DR. BARNES: I should feel like supporting Dr. Durgin, but I am not prepared to vote that in all cases where measles occur fumigation should be practised. I am not sufficiently informed to say that it will prevent an epidemic. I would like to know if Dr. Durgin's experience has been such as to prove that fumigation has stopped or prevented the spread of the disease. For myself, I have not the informa-

tion to warrant me in recommending the city to fumigate in every case.

DR. DURGIN: My point is this: I would like to hear the profession talk about this. I would like to know whether I am going too fast or too slow. Do you think that we are doing all that we ought to do? Do you think the public sentiment would bear us out in going farther than we now go?

DR. BOWDITCH: You don't go at all, as I understand it now.

DR. DURGIN: Yes, we call for the report of the cases, and we get them. Then we send these circulars.

DR. BARNES: Can you prevent children from going to the schools?

DR. DURGIN: We cannot, but we have advised the School Board, and they turn them out.

DR. BOWDITCH: My motion is, that it is proper that the sanitary officials of the city should take notice and care of these cases of measles, as well as of other diseases, such as scarlet fever and small-pox. It does not follow that they should pursue the same course of treatment, for they are very different. I see no reasons why measles should be carried off to the hospital. If we had a physician go to the house where there was a case of measles, he could make arrangements for perfect isolation in the house. That would be all that was necessary in that case.

The question is whether we ought to have any official interference in a case of measles. I think we ought to have some. If death sometimes follows, and there is likely to be an epidemic, we ought to have it. I hope the Society will vote this way. I would like to hear the gentleman who read the paper say from his own experience what he thinks the benefit would have been in his cases, if any, supposing there had been any official treatment.

DR. HODGES: I think in this particular case it would have been very hard to isolate the cases, because all the children went to school in the same building in which they lived, and the first set of children that carried the contagion down to the sick room, practically infected all the children that were there. The isolation in this case was complete so far as it went, because there was no necessity for communication with the outside world. The epidemic was confined to the building in which it originated, and did not spread outside.

Another speaker said: In looking over the records in one of the districts of the Boston Dispensary in 1885, there were sixty cases in April; in November, 1886, thirty-four; and in 1887, fifty-one cases to the present date. I think one great failure in figuring on the deaths is that there are so many cases that are not reported. And I think, as my experience of the matter has been, that I have heard of half as many cases as I have seen, where there was no physician, and where they were undoubted cases of measles, and where the physicians have seen the bronchitis following, when they were called in.

I think the disease must be spread largely at the present time in the public schools, through the inability of the teachers to know that there are cases in the families from which their pupils come. I don't think the public would uphold the Board in the matter. I mean the public in general. I think the public would regard it as being a step too far in advance.

DR. MASON: It is a very important and extensive

subject, and perhaps the Society will take it up again. There are no hospitals or places where children with scarlet fever, diphtheria or measles can be sent. Therefore the only possible way of limiting the epidemics must be through the measures of the Board of Health. I am satisfied that this motion is a very important one, and should be passed. As Dr. Bowditch has made it, it stands as follows: *Moved*: That it is proper, in the opinion of this Society, that the Board of Health should take notice of, and care for, cases of measles, as is done in small-pox and scarlet fever. Is that the wording of the motion, Dr. Bowditch?

DR. BOWDITCH: Yes sir. I would put it exactly upon the same ground as small-pox and scarlet fever. I see no reason why we should not pass it. It leaves it to the sanitary authorities to do just what they think proper. It enables them to go with authority to the house, and give their advice, at any rate, and see that the thing is done.

The motion was carried.

DR. MASON: In the opinion of the chairman it would be well to have this whole matter discussed again, not only in reference to measles, but also in respect to the other contagious diseases. The paper of Dr. Hodges is a very important and interesting one.

DR. J. B. GEROULD, of North Attleboro, Mass., presented a case of

OBJECTIVE TINNITUS AURICUM.

The patient, Mr. E., is thirty-two years old, dark complexion, medium height, a little below average weight. Temperament not especially nervous. Occupation, a farmer. Health good but not robust. Had scarlet fever and pneumonia years ago, fifteen to twenty. Had a severe fall twenty-eight years ago. Entirely recovered from all the above. About three years ago had dizziness after working in the hot sun, was troubled more or less for several months, but not lately.

Several years ago had on slight exertion, trembling spells; would last a half-hour or an hour, was only troubled a short time with them; has had some dyspepsia. Has never had any trouble with ears or hearing until about six months ago, July, 1887, at which time he experienced a *ticking* sound in his ear, which has lasted ever since, only relief during sleep, hearing nearly normal. Physical examination shows a normal ear, excepting the above-mentioned ticking, which is not only subjective but is also objective. It is about as loud as the ticking of a watch, and can be heard at a distance of several feet. I could hear it six feet in a room not especially free from outside sounds; it beats about 160 times a minute, it is nearly but not absolutely regular; distinctly heard in both ears.

DR. VICKERY asked for his theory as to the cause of the sound.

DR. GEROULD. I could find very little on the subject, and could find no theory. I would say that the ticking is about 160 times a minute, but varies somewhat. Once in a while it stops for a few minutes, but is generally continuous. The only thing that I could think of was a spasmodic contraction of the small muscles of the ear. In that case, I should think there would be some movement of the diaphragm which could be seen. In the right ear it is a little louder. I could hardly say whether it is synchronous, but should think it probably is.

DR. LANGMAID asked if there was any loss of hearing.

DR. GEROULD replied that there was not.

DR. J. ORNE GREEN said: I don't think the experience of any one has been very large in these cases. The only objective sounds that I know of that are heard in the ear are of two kinds: There are the murmurs which are vascular, which you get in the ear, and of which I have seen two cases—in 1878 and 1879. These are the only two cases that I have ever seen of that kind where there is a distinct murmur, and that is undoubtedly vascular. These two cases I made the subject of a paper read before the American Otological Society.

In the other class of cases, of which this is an instance, where you get a clicking in the ear, which is entirely different from the murmur. I think these are not so rare as the others. I have seen six or eight in all. They vary somewhat in sound, although in all there is a click distinct from the murmur which you get in the other class of cases, and of this click you have two kinds: You have voluntary and involuntary click. I have seen a number of instances of patients who were able to produce this voluntarily.

I have a professional friend in the country, some twenty miles out of Boston, who can do it in the most wonderful way. He could not describe how he did it when I saw him, but it was perfectly evident. He would produce, by the mere effort of the will, a sharper and more distinct click than this. Sometimes it would be most wonderfully rapid, and then he could make it once or twice in a minute. I have seen a number of others who could do it, but not so effectively.

In him I am satisfied that it was a contraction of the muscles, and I think, in all cases, it is a contraction of the muscles. It is a contraction, in the majority of cases, of the tensor palati muscle, or the spheno-staphyloideus, as it is called by the Germans, and sometimes of the tensor tympani, and sometimes of both. In some of the instances, I have been able to confirm this. When this gentleman that I spoke of does it, you can see a distinct twitching of the palate with every sound. In one case, in addition to the palate, there was a distinct moving in of the drum-membrane. There was evidently a contraction of both the tensor palati and the tensor tympani muscles.

There have been a number of involuntary cases, although this case differs a little in the character of the noise. This is a little more prolonged and less clearly defined click than in most cases that I have seen. This may suggest a little flutter in the tensor palati or tensor tympani, or both. In these involuntary cases, I have once or twice been able to confirm the motion of the palate. It is a very slight motion. You see a little drawing up of the palate that is synchronous with the sound that you get in the ear.

They are interesting cases, particularly from their combination, sometimes, of the two muscles; but I think it can be explained by the anatomy, which is a very curious one. The tensor tympani muscle is inserted along the anterior wall of the Eustachian tube, and also somewhat along the membranous wall. The tensor tympani muscle is in the canal in the upper part, and it is an anatomical fact that the fibres of the muscle often run over and unite with the fibres of the tensor palati muscle. It is very commonly the case, and it is also an interesting fact that both of

the muscles get their motor fibres from the otic ganglion.

I think that is an explanation of these cases. Sometimes you get a contraction of one muscle, sometimes of the other, and sometimes of both. The innervation comes from the same ganglion. With regard to what causes it, I don't think it has ever been established. It has been referred to some contraction of the muscles, but I don't see why we should hear the contraction of these muscles, and not of other muscles. I think, in a good many cases, it is due to the anterior wall of the tube, which is moist, being drawn away from the posterior wall of the tube, just as you can make it with the tongue.

That is the character of the noise in the majority of cases. Once in a while, when you get at the same time the contraction of the tensor tympani, every contraction of that muscle draws the membrane inward a little, and that is associated with a little noise. There you may get a little noise from the drawing inward of the drum-membrane, just as a little rattle of parchment. These are the only explanations that I know anything about.

APPOHAQUI MINERAL WATER.

DR. CUTLER stated that his attention had been called to a new mineral water, the Apohaqui, which has the power of making an emulsion with many of the oils, and seemed to be especially useful in the case of cod-liver oil, as it appeared to take away the taste to a great extent, and patients were enabled to take it more readily, and with less of the unpleasant after-taste.

MR. CORNWALL, agent of the company which is introducing the water spoke briefly of its peculiar qualities. It will emulsify most of the oils, but in no case is it a permanent emulsion. He had been assured by chemists that the quality was more than a saponification, and was due to some peculiar power whose nature the analyst could not detect. The water has been in pretty general use in some of the Montreal hospitals for some months, and is employed in most of their emulsions.

DR. H. L. SMITH did not think the emulsion better than might be made with any alkaline water of an equal strength. In his hands a one per cent. solution of sodium carbonate made a much more perfect and lasting emulsion than the water. A one-tenth per cent. solution produced very nearly the same result. Moreover, he had found by experiment that some of the ordinary waters, as the Apollinaris, Friedrichshall, and Hunyadi, had an equal or even better effect when used in the same way, and the slight bitter or saltish taste that some of them had seemed to be useful in covering the taste of the oil.

MR. CORNWALL was glad of a discussion. The water had had a thorough trial clinically, and good effects were reported. It was advertised to the medical public only, and he hoped for a fair trial.

The following emulsions, produced by the "Apohaqui mineral waters," were placed upon the table for the inspection of those present: Cod-liver oil, $\frac{1}{2}$ oil, $\frac{3}{4}$ water; $\frac{1}{2}$ oil, $\frac{1}{2}$ water; $\frac{3}{4}$ oil, $\frac{1}{4}$ water; $\frac{1}{8}$ oil, $\frac{7}{8}$ water. The following in varying proportions: croton, sandalwood, olive, castor, almond (sweet), neat's-foot, linseed and sperm oils; also balsam of copabia, fir.

It was claimed that the emulsions produced were mechanical and not chemical, that they stood in solu-

tion quite long enough for all practical purposes, that they were easily renewed by a slight shaking action, and that they will keep for a great length of time. In the case of cod-liver oil, it renders it both easily taken and retained by the most delicate stomach, and the water is of a character that renders it useful medicinally with the oil, not having any purgative qualities as is the case with other alkaline waters and also being without the disagreeable flavor, besides producing an emulsion much more readily. The water is pure and simple mineral water as taken from the spring.

The meeting adjourned at 10:15 o'clock.

THE NEW YORK ACADEMY OF MEDICINE.

STATED MEETING, January 19, 1888. DR. A. CAILLE read a paper on

A METHOD OF PROPHYLAXIS IN DIPHTHERIA.

He said that in some families one or more of the members, especially among children, had an attack of diphtheria every spring or autumn, and it had occurred to him that in all probability in such cases the microbes of the disease remained permanently in the system, continuing in a dormant condition until some hyperæmia of the faucial or nasal mucous membrane afforded an opportunity for the diphtheria to break out afresh. The disease was thus propagated by a process of auto-infection.

In order to make a practical test of the correctness of this hypothesis he selected eight individuals, of different ages, all of whom had had diphtheria at least twice, and some of them a considerable number of times, prior to October 1, 1885. All belonged to families which he had known for a long time, and which had continued to occupy the same place of residence. The first thing that he did was to cause all carious teeth to be filled or extracted. He then directed the mouth to be thoroughly rinsed, the throat to be gargled, and the nose to be cleansed three times a day with either a three cent. solution of potassium permanganate, a weak solution of liquor sodæ chlorinatæ, or a saturated solution of boric acid; the different solutions to be alternated with each other from time to time. In very young children the antiseptic solutions were dropped into the nostrils with a pipette. This practice was maintained throughout the year with the exception of the summer months, during which none of the subjects had ever had diphtheria. In addition to these eight cases, he ordered that from ten to fifteen drops of saturated boric acid solution should be dropped into the nostrils of two infants a year old whenever any catarrhal symptoms manifested themselves.

The result of these precautions was that up to the present time not one of the individuals referred to had had an attack of diphtheria since the system of prophylaxis had been inaugurated; although some of them during the time mentioned had been exposed to the disease by other members of the family having it. While this result did not of course afford absolute proof of the prophylactic power of such a plan of procedure, it did go to show that if the nasal and oral cavities were kept clean by means of antiseptic washes, diphtheria was less liable to occur than if no such precautions were resorted to.

It was a fact that hitherto in diphtheria far less attention had been paid to prevention than to the treatment of the disease after it had made its appearance. One reason why it was difficult to employ an intelligent prophylaxis was because of our ignorance in regard to the nature and significance of so-called diphtheria. Since we could not in many instances distinguish between a contagious and a non-contagious sore throat, the problem presented was a very unsatisfactory one to deal with. There was no specific treatment for diphtheria, and in the present state of our knowledge prophylaxis was of more value to the public at large than treatment. Prophylactic measures could be divided into those relating to general sanitary conditions, and those confined within the family. It was an unfortunate fact that in a large city the great majority of the inhabitants were unable to live in perfectly healthy dwellings, and the great importance of individual prophylaxis was therefore obvious.

Dr. Caille then passed in review a large number of works on Practice and on the Diseases of Children, showing that most of the authors scarcely alluded at all to the subject of prophylaxis in connection with diphtheria, while many of the others dismissed it with a few lines. Among those mentioned as devoting proper attention to the matter were J. Lewis Smith and A. Jacobi, and special reference was made to the monograph by the latter on so-called follicular amygdalitis published in 1886. In speaking of the importance of keeping the upper air passages in good condition, with a view to preventing the occurrence of diphtheria, he quoted one writer as saying that a healthy throat bears the same relation to diphtheria that a healthy stomach does to cholera. In a city with densely populated districts, he went on to say, attention to the plumbing and ventilation of apartments and sanitary conditions in general must be supplemented by individual prophylaxis. The overheating of school-houses and dwellings was a constant source of danger, and isolation of those sick with diphtheria was not, as a rule, effected promptly enough. Enlarged tonsils increased the liability to diphtheria; and these should be removed with the knife, or, better, the galvanic cautery. Carious teeth should be extracted or filled, and he thought that provisions should be made by which the poor could have dental cavities filled with cement or amalgam free of charge or at a merely nominal price. He advised that parents should inspect their children's throats every morning before sending them to school, and that all children should be taught how to gargle at an early age. Children with sore throats, however slight the trouble, should not be allowed to go to school, and kissing children on the lips should be forbidden. Parents should be urged to keep the upper air passages of their children in a healthy condition especially if they were peculiarly susceptible to diphtheria. In young children antiseptic solutions could be dropped into the nostrils twice a day, and oftener if there was any nasal catarrh present.

DISCUSSION.

DR. GEORGE T. HARRISON said that he had had such painful experience in the treatment of diphtheria that he was especially glad to hear something in regard to the prophylaxis of the disease, and he believed that the adoption of such precautionary meas-

ures as had been outlined in the paper would be a step in the right direction. He was also glad, he said, to hear Dr. Caille emphasize the danger connected with the so-called follicular amygdalitis, to which the President of the Academy, Dr. Jacobi, had directed attention, as this was a matter in regard to which the profession, as well as the laity needed to be on their guard.

Dr. FRUITNIGHT said that it was a common experience to find that the first case of diphtheria in a family had advanced to a very dangerous degree before the medical attendant was called in, and, consequently, was very likely to prove fatal. It was also noticeable that afterwards in such families the parents themselves often instituted a system of prophylactic measures, making it a daily practice to examine the children's throats, etc.

Dr. S. BARCH said that he should think that the daily washing out of the nose by the insufflation of antiseptic solutions or otherwise was a very dangerous practice, on account of the liability to excite serious ear-trouble, especially if the fluid used was cold.

Dr. T. R. POOLEY said that if the nasal douche were avoided, and warm fluids were used in the form of spray, or by dropping into the nostrils, he did not think there was much risk of causing disease of the middle ear. The safest and best method of washing out the nose was by means of the post-nasal syringe, which could be used with great facility after a little practice.

Dr. CAILLE explained that he did not recommend the employment of cold liquids.

Dr. SEIBERT said that he should like to add a word on the subject of prophylaxis by way of supplement to the excellent suggestions of Dr. Caille, and that was in regard to the importance of keeping children's stomachs in good order, so that the mouth and tongue would be clean. In his experience a furred tongue was always a hot-bed for the development of diphtheritic trouble, and he thought that the candy-shops in the vicinity of the public schools were responsible for a good deal of the diphtheria now so prevalent. These remarks, he said, were prompted to a considerable extent by his experience in the case of his own children.

The PRESIDENT, Dr. JACOBI, said that if he understood the reader of the paper rightly, he held that when a patient has once had diphtheria the germs of the disease are likely to remain secreted in the mucous membrane and lymphatic glands, and he quite agreed with Dr. Caille in this opinion. Many of the cases of diphtheria of the greatest severity are those in which there was immense glandular swelling, with oedema. Such cases were very likely to prove fatal, but if the patient recovered the improvement dated from the time when these symptoms first began to diminish. He felt sure, therefore, that diphtheritic germs were liable to remain in the lymphatics.

If, as had been remarked, the mouth and nose were in a healthy condition, diphtheria was always less liable to occur; while if an epidemic of the disease appeared in a neighborhood the children living there who had a catarrh were especially liable to be attacked. Diphtheria was like crupiselas in this respect. When there was an epidemic of the latter disease in any locality, the slightest scratch was likely to induce an attack of it, while those who were free from any sore or abrasion of the surface escaped.

There was another way in which diphtheria occurred, and in connection with this there was a point of great practical value in its prevention, to which he desired to call attention. It had often been noticed that cases in which it was thought that the attack was about over had a relapse, and in some instances there would be three or four attacks in rapid succession. The reason for this was simply because the room, the bed, the curtains, the carpets had become infected; and he had therefore, made it a rule, wherever this was practicable, to change the room of the patient every two or three days, even if the room to which the removal was made was not as desirable as the one first occupied. In some cases he had found it necessary to have the patient taken out of the house altogether.

Dr. L. EMMETT HOLT said that he should like to ask, for information, whether there were any sufficient data to show that children with enlarged tonsils were more subject to diphtheria than others.

Dr. CAILLE said that his own experience went to show that such children were more liable than others to be attacked, but he believed that as a rule in such cases the disease was of a comparatively mild form.

The PRESIDENT said that the reason why the tonsils were so frequently the primary seat of diphtheria was because they stood so much in the way of the air-current; so that deposits were extremely liable to take place on them. Again, whenever the tonsils were enlarged there was a liability of mucus accumulating behind them. Enlarged tonsils were usually combined with a sub-acute or chronic nasal catarrh or pharyngitis, and the sooner, therefore, the tonsils are reduced and the pharyngitis removed, the better would be the prospect of the child's escaping diphtheria.

Dr. JOSEPH W. WINTERS said that when diphtheria appeared in a family, in addition to enforcing strict isolation, and attending to disinfection and the general sanitary condition of the premises, he inspected the throat of every member of the household daily, and, if there were children, ordered them to take full doses of tincture of chloride of iron (say twenty or more drops, three times a day), and tonic doses of quinine. At the same time, he directed that they should be kept in the open air as much as possible, should sleep in rooms free from pipes connecting with sewers, and be given simple diet, while their digestive organs were maintained in good condition. To this end he usually ordered small doses of mercury as a purgative, two or three times a week. When adopting these precautions, he rarely saw two cases of diphtheria occurring in the same family.

Dr. T. R. POOLEY then read a paper on

THE INDUCTION OF PREMATURE LABOR IN AMAUROSIS AND AMBLYOPIA FROM ALBUMINURIA OF PREGNANCY.

He said that disorders of vision associated with pregnancy had not received the attention which, from their importance, they deserved. Such disorders were more apt to occur in the later months of utero-gestation, and the sight was sometimes permanently lost. Vision might be affected in two ways: *first*, a sudden amaurosis; and, *second*, a gradual impairment, but not complete loss of sight. Like kidney disease, these disorders of vision in pregnancy had been long

known, but not until recently had it been proposed to induce premature delivery for sight alone. As to the propriety of this procedure, and the indications for its adoption, these could best be settled by the coöperation of both obstetricians and ophthalmologists.

The honor of first proposing the induction of premature labor in these cases belonged to Dr. E. G. Loring, of New York, who, in 1883, published the history of a case in which premature labor was brought on for atrophy of the optic nerve depending, apparently, on rapidly recurring pregnancies. The patient was thirty-five years of age at the time, and she was already blind in one eye. Fearing the loss of the other eye also, he proposed the operation. In this case, the usual symptoms of disease of the kidney were entirely wanting; but Dr. Pooley thought it possible that the eye trouble was really dependent on uræmia, as there was no reason why optic neuritis should not occur from obscure renal disease.

Having referred to cases reported by Lee and Eastlake, of England, Holmes, of Chicago, O. W. Moore, Arango, and Callan, of New York, and himself, he went on to say that if the patient were allowed to go to full term, permanent blindness or serious impairment of vision might result; while, if premature labor were induced, or took place spontaneously, improvement always followed, and in some instances the sight was entirely restored. In many cases of the neuro-retinitis of Bright's disease, it seemed as though nature attempted to relieve the patient by bringing on premature labor; but when this did not take place spontaneously, the artificial induction was justifiable, and even demanded.

Having quoted Dr. Loring on the medico-legal aspects of the operation, Dr. Pooley gave his conclusions as follows:

First. In all cases of pregnancy, not only should examinations of the urine be systematically made, but the eyes should be examined with the ophthalmoscope, since in a large proportion of cases where eye troubles exist the patients make no complaint of disorders of vision. Frequently, such troubles can be detected with the ophthalmoscope long before any disease of the kidney is shown in the urine.

Second. In uræmic amaurosis without changes in the eye visible to the ophthalmoscope, even should the usual accompanying symptoms, such as dizziness, nausea, and threatened convulsions, be absent, their supervention is soon to be anticipated; and the immediate induction of premature labor is indicated, without waiting until the life, as well as the sight, of the patient is in danger.

Third. In neuro-retinitis the induction of premature labor is not only justifiable, but urgently demanded. In some instances it is called for even in the earlier months of pregnancy.

Fourth. It is required in cases of eye trouble recurring in successive pregnancies, like Loring's.

Fifth. A woman having once suffered in this way during pregnancy, the relationship of cause and effect should be fully explained both to herself and her husband.

DISCUSSION.

DR. E. G. LORING spoke of the necessity of early ophthalmoscopic examination in all cases of pregnancy, and said that it was a very simple thing, which every practitioner could readily become familiar with, to

detect the retinitis of Bright's disease. Statistics showed the very great frequency with which the retina was affected in pregnancy, and it was important that the trouble should be promptly recognized. This inflammation might begin very early in gestation, while disease of the nerve might not occur until months after labor at term. He then spoke of a very peculiar condition, not associated with *retinitis albuminurica*, which originated not from pregnancy, but from uterine disturbances. Thus, a girl of eighteen was found to be losing the sight of one eye, and an examination revealed the presence of atrophy of the optic nerve on that side. As she was suffering from amenorrhœa, every effort was made to restore the menses, and the measures adopted proved successful. One year later the other eye became affected, and an examination now showed nearly complete atrophy of the optic nerve on one side, with retino-neuritis on the other. Menstruation, which had again ceased, was once more restored, and afterwards she was married and had a child. After she had been nursing the infant for about three months, she began to have trouble again in the sound eye. She was advised to wean the child at once, and when she had done so the menses returned. This patient was now pregnant again.

DR. BARUCH said that he was in accord with Drs. Pooley and Loring, in regard to the propriety of inducing premature labor in the class of cases referred to. Life was as much in danger as the sight, and therefore he thought the necessity for it was perfectly evident. The disorder of vision was a danger-signal which warned the practitioner not to neglect even small symptoms. If amaurosis or amblyopia were present, the condition depended on nephritis, and there were, therefore, many reasons why the pregnancy should be prematurely terminated.

DR. MURRAY thought that all the deductions of the paper were hardly justified by the facts of the case, so far as known; since a very small proportion of even those who suffered from eclampsia, became blind. It seemed to him unnecessary to subject all pregnant women, whether they complained of any disorder of vision or not, to the inconvenience of an ophthalmoscopic examination.

DR. HARRISON said that the paper served to illustrate the close relationship existing between widely different specialties, and that he had been convinced by it that obstetricians should pay more attention to the vision in pregnant women than had hitherto been the case. In practice it was important to make a distinction between *nephritis gravidarum* and *nephritis in gravitate*; the first being a form of disease in which the anatomical and functional disturbances of the kidneys are evolved by the state of pregnancy, while the latter is an interstitial or parenchymatous nephritis, which either existed previous to conception, or has been produced by causes other than pregnancy during the course of the gestation, and in which abortion or premature labor is apt to occur spontaneously. It was evident from what had been said this evening that the ophthalmologist was able to throw considerable light on this subject.

In closing the discussion, Dr. Pooley said he had already written a paper on the subject of eye-disease dependent on uterine disturbances, alluded to by Dr. Loring, in which he had reported some cases observed by himself, and that he had therefore not referred to that subject in his present paper.

Recent Literature.

L'Iodisme. Par ELISABETH N. BRADLEY, Docteur en Médecine de la Faculté de Paris, Membre de la Société Zoologique de Paris. Paris, 1887. pp. 168.

In the preparation of this thesis Dr. Bradley has been an indefatigable collector of the observations of others, a sketch in brief or in detail of one hundred and twenty-six cases being given by her illustrative of disturbances, supposed to be produced upon human tissues by the external or internal use of iodine, iodides, or iodoform.

References are also made in the bibliographical index to articles bearing upon the subject, by three hundred and forty observers. The abundant material thus collected has been systematically arranged under the following divisions. The absorption of iodine by the various tissues of the body; its toxic effects; its action upon the blood, the circulatory, respiratory, digestive, and nervous systems; its effect upon the urine, the skin, and the eyes; and the subjective symptoms caused by it. Dr. Bradley makes no claim to personal experience with her subject, and it may be fairly stated that she has not sufficiently weighed the relative value of the vast bulk of evidence presented in support of some of the conclusions she presents. In many instances cited it might be held that symptoms adduced by observers as caused by iodine, were incident to the disease for which the drug was administered. Her conclusions are as follows:

(1) Iodine is absorbed by the skin, the mucous and serous membranes. It is transported throughout the body by the circulation, and is eliminated by all the glands.

(2) The various preparations of iodine are not absorbed by the skin, the mucous and serous membranes while intact, before undergoing a decomposition by which the iodine is set free.

(3) In certain conditions of loss of vitality, and particularly in case of cardiac and renal affections, where there is morbid nervous irritability, there may be an increase of the physiological phenomena produced by the iodine, with symptoms of poisoning.

(4) Symptoms of poisoning by iodine indicate a disturbance of all the functions of the organism, with a predominance in its most feeble points. They may follow its long-continued use, or show themselves at the beginning of treatment. In either case they may disclose themselves suddenly, or develop gradually.

(5) Among the most constant symptoms of poisoning is an excessive quickening of the pulse, which likewise becomes feeble, dwindling beneath the finger and even disappearing in grave cases.

(6) This state of the pulse is not accompanied by a parallel elevation of temperature, which may remain normal, or even fall below the normal.

(7) This lack of parallelism between the pulse and the temperature may be explained by the disordered state of the nerve centres.

(8) The disturbances of circulation are also shown by oedema, which may be confined to the eyelids in mild cases, or extend over the whole body in grave cases, as well as to the glottis, lungs and brain.

(9) The blood is altered in character, and hæmatisis does not take place in natural ways.

(10) The disturbances of circulation are followed by changes in the quantity and quality of the urine.

There are often albuminuria, nephritis, and even hæmaturia. These symptoms are preceded by a diminution in the amount of urine, or anuria even.

(11) The nervous symptoms are those which belong in common to anæmia and to cerebral congestion, and assume sometimes the form of uræmic convulsions and coma, and sometimes that of hypochondria and general paralysis.

(12) The lungs share in the general disturbance, and in addition to symptoms resulting more or less directly from the derangements of circulation, such as bronchitis, oedema, hæmoptysis, etc., dyspnoea, irregular respiration, and apnoea often occur.

(13) The disturbances of the nervous system are manifested by anorexia, morbid appetite, nausea, vomiting, gastric and intestinal pains, diarrhoea or constipation.

(14) The nutrition of the skin is impaired. Capillary spasm is followed by passive dilatation. It becomes the seat of various forms of eruption, erythema, urticaria, papular-bullous efflorescences, and hæmorrhagic lesions.

(15) The joints may be affected, becoming painful and swollen.

The work may be regarded as a valuable repository of observations in relation to one of the most important and most greatly abused drugs of the materia medica.

Photographic Illustrations of the Anatomy of the Human Ear together with Pathological Conditions of the Drum-Membrane. By B. ALEXANDER RANDALL, A.M., M.D., and HENRY LEE MORSE, B.A., M.D. Philadelphia: P. Blakiston, Son & Co. 1887.

This atlas, which may be said to be a continuation and extension of a method of illustration introduced by Rüdinger, in his famous "Atlas of the Human Ear," published in Munich in 1866, consists of thirty-nine photographs of the osseous anatomy, twenty-three of preparations of the drum-membrane, and twelve of microscopic sections, together with a descriptive text. The subjects, both of normal and pathological anatomy are well chosen, and the photographs themselves are beautiful reproductions of objects which are by no means well adapted to photography, but which have, by a careful illumination, been, in most cases, brought out most distinctly. The absence of all retouching assures absolute accuracy and the anatomical names directly upon the plates, make ready reference easy. Some of the photographs of pathological conditions of the drum-membrane show very finely a very successful treatment of a difficult subject.

The text is succinct but very accurate, and all sufficient for description.

With Hinton's atlas of water-colors done by hand, of the drum-membrane in health and disease, Rüdinger's atlas of the normal anatomy, and this new work, each supplementing the other, the teacher is supplied with a series of illustrations invaluable in his work of demonstrating; and the student or practitioner is afforded a collection of pictures, clear and very useful for reference, such as are not surpassed by illustrations of any region of anatomy.

—The University of Bologna has issued invitations to her sister, or perhaps we should rather say, daughter universities, to attend the celebration on the 12th of June next, of her *eighth century*.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, FEBRUARY 2, 1888.

*A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.**SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States and Canada; \$6.00 per year for all foreign countries belonging to the Postal Union.**All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 94 Boylston Street.**All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the "Manager of the Business Department," Medical and Surgical Journal, 94 Boylston Street.**Remittances should be made by money-order, draft, or registered letter, payable to*CUPPLES AND HURD,
94 BOYLSTON STREET, BOSTON, MASS.

THE COLD-BATH TREATMENT OF FEVERS.

THE modern use of cold applications in exanthematous and continued fevers may almost be said to date from Currie, who made a specialty of this treatment toward the close of the last century. Currie preferred cold affusions to cold baths. Then came Giannini, of Milan, about the beginning of this century, who employed cold baths, defended his practice on scientific grounds, and was the real founder of Brand's method. In 1812, Récamier, in the Hôtel Dieu, Paris, treated typhoid fever by cold baths; patients were kept fifteen minutes at a time in a bath of 68° to 70° F., and were given two or three baths a day. In 1822, Fröhlich, in Germany, published a prize treatise on the treatment of acute febrile affections by cold water. He reported a number of successful cases, and claimed superior efficacy for this mode of treatment. About the year 1843, we find Scoutteten and the physicians of the Faculty of Strasbourg employing the hydrotherapeutic procedures of Priessnitz in typhoid fever; and, a few years later, Jacquez, of Lure, and Leroy, of Bethune, published valuable monographs on the refrigerant treatment of fevers.

The first work of Brand, who is distinguished by the precision and rigorosity with which he has conducted the hydrotherapeutic management of fevers, and whose name is now everywhere connected with this mode of treatment, was published in 1861; and since that date, a succession of treatises from the same hand, from 1861 to 1877, have appeared on this subject. This method soon became generally adopted throughout Germany, where it was advocated by Liebermeister and other of the leading medical authorities of that empire. It was introduced into France by Glénard about the year 1871, and has been the dominant therapeutic system at the hospitals of Lyons, although not adopted to any extent in the other French hospitals. It need hardly be said that the cold-water treatment of fevers has never become popular in this country or in England.

At the onset of his clinical experimentation, Brand made use of affusions and of the partial half-bath of

Priessnitz; in his later publications he abandons all these hydrotherapeutic procedures, and replaces them by the cold bath. The temperature of the patient is taken every three hours, night and day, and, whenever it is found to be above 103° F., the patient is plunged into a cold bath. Brand has claimed for this method, when carried out in all its rigorosity, and from the very inception of the fever, extraordinary results.

At the close of a series of "conférences" on "hydrotherapy" in recent numbers of the *Bulletin Général de Thérapeutique*, and *Therapeutic Gazette*, Du Jardin-Beaumetz, to whom we are indebted for the above concise summary of facts, takes up the cold water treatment of fevers. The fact of a physiological depression of temperature, amounting to several degrees, under the influence of cold baths is unquestionable; the main question, however, according to Beaumetz, is whether this artificial bringing down of the fever heat does any good or not. This inquiry must be answered in the negative if it shall be found, on careful experimentation, that the production of heat in the organism is increased, rather than diminished, by the cold baths. It seems to have been sufficiently demonstrated that the danger from hyperthermia results not so much from the elevation of the temperature itself, as from the exaggerated activity of the phenomena of organic combustion which produce this hyperthermia, and that the real indication is to combat this excessive thermogenesis. Whether cold baths fulfil this indication or not, must be determined by experimentation.

Within the past few years, careful series of experiments have been made by Frédéricq, of Liège, and by Quinquand, of Paris, which seem definitely to have settled the dispute. Frédéricq made use of the well-known apparatus of Regnault and Reiset, devised for the study of the gases of respiration. He modified the apparatus so as to make it applicable to man, in order to show that cold, "when acting on the cutaneous surface of the human subject, markedly augments the absorption of oxygen and the production of carbonic acid, and consequently, the production of heat." Frédéricq concludes that, far from slowing the interstitial combustions, cold powerfully excites them.

Quinquand, by very careful experiments made on animals, confirms the conclusions at which Frédéricq had arrived by his experiments on man. He also states that, under the influence of cold baths, both the absorption of oxygen and the elimination of carbonic acid are markedly increased. Then, taking up the study of the influence of cold baths on the elementary nutrition by the aid of the simultaneous analysis of the gases of the arterial and venous blood of the peripheral circulation and of the right heart, Quinquand finds that cold baths augment the activity of the interstitial combustions. Completing his researches by calorimetric studies, he has, lastly, shown that the heat-units emitted in a given time increase under the influence of cold baths.

"These accurate experiments," says Beaumetz,

"ought henceforth to settle this question; and we are now warranted in affirming, as a physiological truth, that under the influence of cold baths the organic combustions are enhanced, on condition, always, that the refrigeration shall not exceed certain limits, and shall not reduce the rectal temperature of the subject under experimentation below 86° F."

It would seem, then, that apart from the tonic effects of the baths (which are doubtless considerable) but a sorry benefit can be derived from a mode of treatment which increases the combustions of the economy. This it is which explains the superior efficacy of antithermic medicines, such as acetanilide and antipyrine, which in some yet unknown way restrain thermogenesis. A ten-grain dose of antipyrine or half the quantity of antifebrine, given to an adult patient, and repeated every hour till the usual physiological effects are obtained, will bring down the pyrexical temperature quite as certainly as a cold bath, and with greater safety, comfort and benefit to the patient.

TARIFF REFORM AND THE DOCTOR.

THE subject of taxes on imports has gained such political significance of late, that doubtless most of those who read the above title will feel some mild impatience that a journal devoted to professional subjects should dare mention anything connected with "politics." But the Georgia Medical Society has boldly taken the matter in hand, and, through its corresponding secretary, makes an appeal to the medical journals of the country to use their influence in support of the movement to remove the import duties from all medical and surgical instruments and appliances, and the circular contains the following "statement of facts":

(1) Physicians are at the mercy of instrument makers in regard to price, make and quality of finish, because of the lack of sufficient competition.

(2) The price of instruments made in this country, is out of proportion to that paid for similar instruments on the Continent of Europe.

(3) Surgical instruments and appliances are so costly that but few doctors entering the profession can provide themselves with an outfit adequate to carry on a general practice. At present prices it is impossible for a country physician's income to sustain his investing in costly instruments and as a result many simple cases, such as retention of urine, foreign bodies in nose or throat, deep-seated abscesses, etc., all of which could be relieved at once with the proper instruments, must either die from the immediate cause or from the effects of time lost in seeking skillful manipulation, or else they are frequently crippled and disfigured, because the most intelligent help though patiently given is itself crippled for want of proper instruments.

(4) The cheaper grades of instruments are either antiquated or so poorly made that they may prove a cause of failure in operations, sapping as it were, the natural inclinations to surgery in its inception.

(5) European instruments are from twenty-five to seventy-five per cent. cheaper than ours and their introduction into the market will enable the mass of doctors to buy those of prime necessity, will bring down the price of home-made appliances and oblige the makers to use good material and put a better finish to the work.

(6) The removal of import duties on surgical and other instruments used by the profession and on medicines in general, will produce the same results as we all know it did on the article of quinine.

It certainly seems a little curious that a profession, which maintains as emphatically as does ours, that no invention intended for use by the profession shall be patented by any member of it—thus making the humanitarian side of the profession paramount to the commercial—should be deliberately hampered by the Government in procuring, wherever it may, the instruments valuable in treating the sick.

At the present moment, the young physician who desires to send home to one of his seniors the latest English book on a subject in which he is interested, obliges the receiver to visit the Custom House and contribute to the public revenue before he can give his patients the advantage of the wisdom which the book is supposed to contain. And the public-spirited individual who imports certain instruments impossible to be obtained in this country—instruments for which the demand is so small that the unrestricted patronage of the world can scarcely prove remunerative to the manufacturer—is mulcted by Uncle Sam of a sum which nearly doubles the original cost.

The results of any change in the tariff we do not pretend to definitely predict. If, as the Georgia Society's circular intimates, the abolition of the impost on surgical instruments would do away with untrustworthy instruments, the change would be a welcome one indeed, but the Georgia Society might be supposed from its manifesto, to hold the idea that all foreign surgical instruments are good. It is to be feared that one effect would be to flood the country with still more unreliable instruments of cheap foreign manufacture. Such a reform in the tariff would undoubtedly cause some changes in the details of the business of instrument makers and dealers. Our faith in the skill of our surgical instrument-makers is sufficient to make us feel that they would, on the whole, suffer no detriment. It might prove cheaper to import certain articles than to manufacture, exactly as certain instruments like scissors are largely imported now, but the general demand will be for instruments differing in some little particular from the European models—a demand which only home manufacturers can supply.

No one can estimate the good to be gained by such freedom from hampering restrictions as the Georgia Society advocates. Anything that benefits the profession ought to benefit the public, and we trust we shall soon see not only surgical instruments, but medical books, and, perhaps, certain utensils used in chemical manipulations and not manufactured in this country, admitted free of all duty. The tariff is undoubtedly in many ways a very great nuisance, and in some a great injury to the country.

THE BENEFITS OF HYPNOTISM IN HYSTERIA.

FROM the article of Gilles de la Tourette in the February *North American Review*, an article which "has been read and approved by Professor Charcot," we learn that hypnotism is turned to great account at

the Salpêtrière, in the treatment of hysteria. "For ten years and more," says this writer, "it has been found at this Infirmary that the hypnotizing séances, oft repeated and methodically conducted, have in hysterical patients much diminished the frequency of the attacks." To prevent a threatened attack of hysteria the physicians of the Salpêtrière, it seems, often put women into the lethargic state and allow them to remain in this state upwards of twelve hours, it being better to put an hysterical patient asleep than to allow a paroxysm to come on with all its unpleasant consequences. When the hysterical patient is awakened after a certain time, she will have escaped the convulsions.

"Again," continues this writer, "it is known that an hysterical seizure sometimes leaves behind, after it has passed away, certain complications that may become permanent affections, of the nature of contractures or paralysis. Even when these complications exist, nay, especially where they exist, hypnotization may have the happiest effects. By calling into action the neuro-muscular-super-excitability, the lethargic patient is relieved of the contractures through excitation of the antagonist muscles. Finally, suggestion is of great avail in the special type of paralysis studied by Dr. Russel Reynolds. Suggestion may be effective even where the paralysis has continued for some time, and we have successfully treated cases of more than one year's standing."

This writer affirms hypnotism to be an agent which may do much harm, that it is not to be trifled with, that in persons predisposed to hysteria it may develop that disorder, and that it "properly belongs to the domain" of medicine, out of which it should never be taken. He has nothing but condemnation for those mountebanks "who knowing nothing of medical science, go about magnetizing persons either so regardless of their own health, or so ignorant of the danger, as to submit to such practices." It is by such exhibitions, which are largely fraud and humbug, that the general public, and even the medical profession in this country, have been chiefly indoctrinated into the mysteries of hypnotism, concerning which the average physician manifests much scepticism and little interest, while, at the same time, wondering at the therapeutic results claimed for hypnotism by his confrères the other side of the water.

MEDICAL NOTES.

—Don Raphaël Alcáde y Buril has been appointed dentist to his august Majesty the king of Spain. Salary, per annum, \$500; duties, to inspect weekly the royal teeth, to clean and fill when necessary. The royal teeth are not at present *in esse*, but *in futuro*. Their owner, however, must now be nearing the period of his first dentition.

—A *propos* of mental automatism it is related of the late Mr. Chippendale that, when in his eightieth year, he played the part of old Hardcastle in "She Stoops to Conquer" at Edinburgh, and in the very

best manner, while his mind was so affected that, as was subsequently learned, he was not even conscious of where he was playing. His hundreds of performances of the part had rendered him a perfect automaton in its representation.

—The Maharajah of Darbhanga, in Bengal, has established a hospital and dispensary for female patients near his ancestral seat in the district of Darbhanga, Behar, and is erecting new quarters for its accommodation, at a cost of 55,000 rupees, in connection with Lady Dufferin's Medical Aid for Women fund.

BOSTON AND NEW ENGLAND.

—A correspondent (whose sex may be conjectured as possibly female) writes to the daily press in criticism of the fact that the trustees and the visiting and house staff of the Boston Lying-in Hospital are all males. She concludes with the following suggestion, whose carrying out would involve not only important architectural alterations in the lying-in room, but some modifications in the natural course of labor, in order that "all competent women physicians" should either simultaneously or consecutively attend the patients. "The trustees of the Lying-in Hospital should see to it," says the correspondent, "that all competent women physicians are admitted to the care and treatment of the unfortunate women whom stress of circumstances drives to this temporary shelter."

—Mrs. Ellen Spellman, probably the oldest person in New Hampshire, died in Concord, Saturday night, aged 104 years. She was a native of Ireland, and came to this country twenty-five years ago, since which time she has lived in Concord. Mrs. Spellman always enjoyed excellent health, never having any serious illness until about a month since. When 102 years of age, she walked a distance of four miles.

NEW YORK.

—The building of the new Croton Aqueduct was attended, during the year 1887, with 64 serious accidents to workmen along the line, 27 of which resulted in death, and 37 in serious injury. From the beginning of the work to January 1st of this year, 86 men have been killed, and 144 seriously injured, making a total to the date mentioned of 230 serious accidents.

—January 27th, the reported receipts of the Hospital Saturday and Sunday Collection amounted to \$46,868.

—Mr. Elbridge T. Gerry, who attended the hanging of Daniel Driscoll, a murderer, at the Tombs Prison, January 23d, as a member of the Commission appointed by the Legislature to report on the most humane and practical method of executing criminals, is said to have remarked concerning it, that if all public executions were conducted as skillfully, decently, and quickly as this one, there would undoubtedly be less objection to the present system than now exists. In this instance death was instantaneous, the man's

neck being broken, and only ten minutes elapsed from the time he entered the prison-yard where the gallows was situated until his body was lowered for the attending physicians to make their examination.

—The Sanitary Aid Society held its annual meeting January 23d, when it was reported that since the establishment of its lodging-house in Dover Street, two and a half years ago, over seventy thousand lodgings, at ten cents each, had been given. The place is self-sustaining, and is not adequate to accommodate half the applicants who come to it, so that the Society decided to establish another lodging-house, probably in the Bowery.

—During the past two months there have been a considerable number of cases of small-pox in Brooklyn, and the health authorities have been thought by some to be negligent of their duty under the circumstances, especially as regards cases in lodging-houses. The Department claims, however, that it has employed all the agencies at its command for the suppression of the disease, and that the outbreak is diminishing.

—At Utica, there has recently died, on the second anniversary of the death of a maiden sister, at the age of ninety-nine, Mrs. Anna Parmlee, who is said to have been born in Vermont, April 29, 1784.

—Mayor Hewitt has just transmitted his annual message to the Board of Aldermen, and, in referring in it to the Department of Charities and Correction, he states that while the investigation of the State Board of Charities served to show that the alleged abuses in it had been greatly exaggerated, it was made equally clear that abuses did exist which needed prompt relief. The over-crowding of insane patients was to some extent relieved by the immediate leasing from the Commissioners of Emigration of some unoccupied buildings on Ward's Island. An appropriation was also made for the beginning of operations on the farm of 1,000 acres which had been purchased at Islip, Long Island, for the accommodation of the milder cases of insanity. Having mentioned that the Board of Estimate and Apportionment have increased the usual appropriation, in order to meet the requirements specified by the State Board of Charities, he goes on to say that benevolent and intelligent persons have urged that there ought to be made a complete separation between the criminals, the paupers, the sick, the insane, and the children; and that instead of one management for all of these classes, there should be, at least, four boards of administration, each charged with the care of a single class, while the various classes should be located in different places, so that there might be no possibility of intercourse between them. At present, Mr. Hewitt does not think that the city authorities are prepared for the radical changes thus recommended, but, the advice and criticism of consulting boards of visitors being always advantageous and most desirable, he suggests that advisory committees of benevolent men and women be secured to cooperate with the present Com-

missioners in framing suitable rules, and in keeping institutions in the best possible condition. As matters now stand, therefore, he thinks it will be best for the Mayor to appoint such voluntary advisory committees, one for each of the several classes specified, to inspect the institutions at stated intervals, and to give to the Commissioners the benefit of their observations and counsel. After the effect of the increased expenditures now authorized has been felt, and the experience of the advisory committees for the coming year ascertained, he thinks it will be possible to mature measures looking to the best arrangements for the general good, and he does not doubt that very great improvements will result from the careful study of the problem by the competent citizens whose services he hopes to enlist in this benevolent work.

Miscellany.

STATIC EQUILIBRIUM.

As the result of experiments on 150 healthy adult males between the ages of 20 and 40, Drs. William N. Bullard and E. G. Brackett find the amount of motion of the head during the space of one minute, while the subject is standing erect and unsupported, to be as follows:

Antero-posterior motion, with the eyes open: Average, 3.826 cm.; greatest in any case, 9.2 cm.; least, 0.8 cm.

Antero-posterior motion, with the eyes shut: Average, 3.475 cm.; greatest in any case, 8.9 cm.; least, 1.2 cm.

Lateral motion, with eyes open: Average, 1.951 cm.; greatest in any case, 5.4 cm.; least, 0.6 cm.

Lateral motion, with eyes closed: Average, 1.963 cm.; greatest, 6.8 cm.; least, 0.4 cm.

A paper giving a full account of these important experiments will, we understand, be published shortly.

DEATH RATES IN PROVIDENCE, R. I.

ACCORDING to the report for December issued from the City Registrar's office of Providence, R. I., the number of deaths in that city in each of the last three months of each of the last five years, and the total mortality for each year, was as follows:

	1887	1888	1885	1884	1883
October . . .	244	217	156	205	195
November . . .	191	156	162	203	165
December . . .	237	167	161	195	184
Last three months . . .	672	540	479	603	544
Whole Year . . .	2,610	2,335	2,164	2,233	2,328

The number of deaths in 1887 was greater than in 1886 in every month of the year except in August. In 1887 the number of deaths exceeded 200 in every month except February, June and November. The number of deaths in 1887 was 255 greater than in 1886, and 446 greater than in 1885.

The following table shows the number of deaths, and the annual rate of mortality in Providence, in each month of each of the last two years, calling the population 120,000 in 1886, and 121,500 in 1887.

	1887		1886	
	Deaths.	Rate.	Deaths.	Rate.
January	216	21.33	183	18.50
February	189	19.65	171	17.40
March	216	21.33	215	21.50
First three months	631	20.77	574	19.12
April	215	21.25	190	19.00
May	208	20.54	168	16.80
June	170	16.79	163	16.50
Second three months	693	19.52	623	17.45
First six months	1,224	20.15	1,097	18.28
July	222	22.91	222	22.20
August	226	22.28	268	26.80
September	226	22.32	268	26.80
Third three months	714	23.50	698	23.27
First nine months	1,938	21.27	1,795	19.94
October	241	24.10	217	21.70
November	191	18.86	156	15.60
December	237	23.31	187	18.70
Fourth three months	672	22.12	660	22.12
Whole year	2,610	21.48	2,355	19.62

ECHINOCOCCUS OF THE UTERUS.

At a recent meeting of the Royal Society of Physicians of Budapesth, as we learn from the Vienna correspondent of the *Medical Press and Circular*, Primarius Dr. Elischer demonstrated an interesting case of echinococcus of the uterus. The woman, aged twenty-five, had twice aborted during the last three months; she menstruated very irregularly, which she was disposed to ascribe to an abdominal tumor, from which she had been suffering for the past two years. On admission into the Elizabeth Hospital, on June 1, 1887, metrorrhagia and the above-mentioned tumor were found, and an enlargement of the uterus was noticed to so unusual an extent that the possibility of pregnancy could not be excluded. The patient, indeed, aborted, after five days, with an embryo three weeks old. The course of the whole process was quite favorable, and the patient returned to her home.

On the 21st of August she came again, as the tumor had grown, and caused her great pain. A nodular tumor of the size of the head of a fœtus, which derived its origin from the posterior surface of the uterus, was diagnosed (fibro-myoma), and laparotomy was performed on the 25th of August. After opening the abdominal cavity, a solid tumor of the size of the head of a fœtus, with two knobs, which adhered by means of false membranes to the uterus, was detected. Moreover, several adhesions of the tumor with the bladder, the intestines, and the ligaments of the oviducts were present. After a piece of the epiploon which covered the tumor was removed, Dr. Elischer tried to detach the swelling; this was not, however, possible, owing to the numerous adhesions. To diminish the size of the tumor, puncture was tried, and a clear fluid containing 320 echinococcus-cysts discharged. The operator had to desist from the detachment of the mother-cyst, as the attempts which had been made gave rise to considerable hæmorrhage of the parenchyma of the uterus. Owing to this condition, the cyst was attached to the abdominal walls, and the cavity was drained. The abdominal wound was closed in the same way, as in case of myotomy. The course of the patient after the operation was excellent. By means of daily washings, several daughter-cysts, and at last, also the mother-cyst, could be removed. Fever did not occur until the suturing-canals of the silk threads began to suppurate. The cystic

cavity was closed, except for a small space, through which only the smallest-sized drainage-tube might be introduced.

Dr. Elischer remarked, with reference to this case, that the occurrence of echinococcus cysts in the genital organs was very rare; so far as he was acquainted with the literature of the subject, no case of echinococcus of the uterus was hitherto on record. The cases of Spencer Wells, Geissel, Scheerenberg, Witzel, and Slayvansky, as well as those of Freund, related to echinococcus in the abdominal cavity. Only the cases of Thornton and Olhausen were to be looked upon as echinococci of the genitals. In the case of Olhausen, the echinococcus adhered to the uterus by means of a membrane. In the case of Dr. Elischer, the cyst filled the whole cavity of Douglas, and was attached by means of adhesions to the bladder, the ligaments, the epiploon, and the intestines. The seat of the echinococcus, however, was subperitoneal, which became evident by the strong hæmorrhage of the uterine parenchyma when attempts at detecting the mother-cysts were made.

A SINGULAR CASE OF YAWNING AND SNEEZING.

We notice in the *Medical Press and Circular*, January 11, 1888, the report of a remarkable case of the above affections occurring under the care of Dr. Robert J. Lee, at the London Temperance Hospital.

The patient was a girl of fifteen years of age, well-developed, and of prepossessing looks, and of cheerful and healthy appearance. She stated that five weeks before she came under notice, she had had one of her double teeth removed, without any particular difficulty and without anæsthetic. Half an hour after the operation she began to yawn, and up to the time when first seen the yawning had been constant and uncontrollable; that is to say, for a period of five weeks she was constantly yawning, except in her sleep, which was naturally quiet, and not unusually prolonged.

She complained of no pain and no feeling of illness, and was apparently rather inclined to be amused at her condition than otherwise. This might partly have been due to the effect which she produced upon those near her, for that singular provocation to yawning which is induced in others by the influence of sympathy, was very distinctly seen among the nurses and patients in the same ward with this girl. The tooth which had been removed was the premolar in the lower jaw on the right side. The gum was carefully examined by Dr. Lee and Dr. Gould, but no evidence of any irritation could be found. There was no derangement of the normal functions to be noted, no menstrual disturbance or other sexual derangement. Various observations were made of the temperature, of the condition of the kidneys, and other organs with negative results. The circulation was regular and quiet, and there was no account obtainable in any form of hysteric paroxysm. She was treated with full doses of bromide of potassium and belladonna, without any decided effect for a few days, when the attacks of yawning changed to attacks of sneezing rather suddenly. One paroxysm followed the other much in the same way as we observe in those ordinary attacks, to the number of two, or generally three, which are very familiar to us; that is to say, there

was about the same interval of time between them, and there was hardly sufficient rest for more than a few words to be spoken, before speech was interrupted by the succeeding paroxysm. This condition persisted like the yawning, the whole day, and the effect of the sneezing seemed to be more distressing and exhausting than the former. The patient was chloroformed once, with the result that during insensibility the sneezing ceased, but on recovering sensibility the first thing she did was to sneeze with unusual violence and frequency. A communication was addressed to Professor Charcot, to obtain the advantage of his experience, so as to direct the future treatment of the case. While awaiting his reply the patient was kept in bed and treated with half-drachm doses of bromine of ammonium, and in the course of a week or so the sneezing ceased. M. Charcot, in reply, referred to an interesting lecture he had given on Neuropathic Sneezings, which he had delivered between two and three years before on a case similar to this, and gave several other references.

Shortly after, in consequence of severe pain in a decayed molar tooth on the opposite side to that from which the former tooth was removed, she underwent a similar operation. In the course of two days the yawning began again, and she was again treated with bromide of ammonium and kept in bed. On this occasion the yawning continued for a week, and then entirely ceased, and she had no other trouble of any kind up to the time she left the hospital.

OBITUARY. JOHN DEAN, M.D., M.M.S.S.

BORN 1831, DIED 1888.

IF Dr. Dean had died some twenty or more years ago, the announcement of his death would have occasioned a sensation in scientific circles both at home and abroad. But ill health had so completely overcome him that he has long since passed out of the sight and out of the mind of the scientific world, and it is only to his personal friends that his death gives any pang. Those interested in the history of scientific work in America will be thankful to us for collecting some of the facts of the life of one who not only was the pioneer in American microscopic studies of the structure of the central nervous system, but who stood among the first workers in the world in that, as yet, little trodden path.

John Dean, the son of William and Lydia Dean, was born at Salem, Mass., December 21, 1831. He was educated in private schools and did not go to college, but went abroad for a year or so in 1850. He studied chemistry with Professor Horsford at the Harvard Scientific School in 1852-53, and soon after went to Germany to pursue his studies in that branch. He took the degree of Ph. D., at the University at Göttingen. He entered the Harvard Medical School in 1856, and graduated in 1860. There is still in the Museum a beautiful dissection of nerves bearing his name and that of Charles F. Crehore. During his medical studies he must have found time for original research, for his first important work on the "Lumbar Enlargement of the Spinal Cord," was presented before the Academy of Arts and Sciences, by Prof. Jeffries Wyman, on November 14, 1860. A still larger work illustrated by photographs of his sections as well as by plates, was that on the "Gray Substance of the Medulla Oblongata and Trapezium," published by the Smithsonian Institution in 1864. His reputation was now made, and in a field which in America, at least, was an absolutely new one. Unfortunately his health now failed him. He suffered from nervous exhaustion, and from chronic bronchitis and asthma, from which since that time he was rarely free, and which

repeatedly brought him into a critical condition. For many years he has been a complete invalid.

He married in 1859, Miss Eliza Philbrick Southwick, whose care of him was tender and constant till his death. He went abroad for several years, and made repeated fruitless attempts to resume his work. At last, feeling that it was hopeless, some twelve years ago, being at the time in America, he gave his entire scientific library which contained files of uncommon scientific periodicals and many rare and costly works on the nervous system, to the Physiological Department of the Harvard Medical School and at the same time his instruments and a choice collection of microscopic specimens. He went abroad for the last time in the spring or summer of 1882, and since then his home has been in Florence, where he died January 13, 1888, apparently from an acute attack of bronchitis.

It was a severe blow to him to have to recognize that he must give up his scientific labors; but he bore it with the patience that was characteristic of him and took pleasure in thinking that he had so disposed of his books and preparations that they would be of use to others. Dr. Dean was of a most amiable character; affectionate, modest and very patient. Many years ago, both Dr. and Mrs. Dean became converts to the Roman Catholic Church, of which he died a zealous and devout member.

OBITUARY. ASA GRAY, M.D., LL.D., ETC.

DR. ASA GRAY, Fisher Professor of Natural History and Director of the Herbarium of Harvard University, died at Cambridge, January 30th, in the seventy-eighth year of his age. Dr. Gray was born in Paris, Oneida County, N. Y., November 18, 1810. He took his medical degree in 1831, but only practised the profession a short time. He soon entered ardently upon the study of botany with Dr. John Torrey. He was appointed in 1834, botanist to the United States exploring expedition which was preparing to be sent out under command of Capt. Wilkes, but resigned in 1837, before the expedition, which encountered many delays, actually started. He went to Cambridge as Fisher Professor of Natural History in 1842.

He was one of the original members of the National Academy of Sciences, and had been at different times regent of the Smithsonian Institution, president of the American Academy of Arts and Sciences, and of the Association for the Advancement of Sciences, and an editor of the *American Journal of Science*. He was a member of almost all the principal scientific societies in this country, in Great Britain and on the Continent of Europe.

Dr. Gray has left a name which will be permanently associated with American botany, a field in which he had no rival. He was almost equally well known on both sides of the Atlantic, not merely in connection with those subjects, to which he had especially devoted himself, but in a still larger measure, as a sound reasoner, a shrewd thinker, a kind friend and a charming companion.

OBITUARY. GEORGE A. CROSBY, M.D.

DR. GEORGE A. CROSBY died at Manchester, N. H., January 30th, at the age of fifty-six years. He was born in Lowell, Mass., in 1831, graduated from Dartmouth College in 1852, and took his medical degree in 1855. He spent some years at the Isthmus of Panama and in Peru, but, at the outbreak of the War of the Rebellion, offered his professional services to the United States Government, and they were accepted. Since the War, he has practised his profession with ample success in Manchester, N. H. He had been President of the New Hampshire Medical Society, and was a member of the Manchester Board of Health. Dr. Crosby's family name is well known in the medical history of New Hampshire and New England.

A NEW ASPIRATING APPARATUS.

A PARIS correspondent of the American *Lancet* gives a description of a new appliance for thoracentesis invented by Dr. Ruault, and designed to avoid too sudden or too great lowering of the intra-pleural pressure. The description of the instrument is to be found in the *Comptes Rendus* of the Société de Biologie, July 30th.

To an ordinary wide-mouthed flask, filled two-thirds with water, is adapted an India-rubber cork pierced with two holes. Through these holes are passed two glass tubes, one reaching nearly to the bottom of the flask, and the other extending only a little below the bottom of the cork. To the upper end of this latter is fixed an india-rubber tube, about two feet long, having a stop-cock near to its extremity, which is destined to be adapted to a trocar of Professor Potain's apparatus for the operation of thoracentesis. To the other and longer glass tube is fixed an india-rubber tube of about four feet long, reaching down into a vessel on the floor destined to receive the liquid evacuated from the pleura. The apparatus is now complete, and being placed upon a table near the bed of the patient about to be operated upon, is ready for use. On blowing through the tube which carries the stop-cock, siphon formed by the other two tubes is primed. A small quantity of water is allowed to run out until there is sufficient in the lower vessel to cover the end of the longer india-rubber tube. The stop-cock is then closed. The water will continue to flow for a short

time until the pressure within the flask is inferior to that of the atmosphere by about six centimetres of mercury. The trocar can now be adjusted and the puncture made in the usual manner. On opening the stop-cock the liquid from the pleura will flow into the bottle and mix with the water. But as fast as the quantity of liquid in the bottle augments, the pressure above increases, and the siphon is again primed. The liquid, after passing through the bottle, continues to flow into the lower vessel until the operation is terminated. If the vessel is wide enough for the differences of level to be only slightly sensible, the pressure in the aspirating flask will remain about the same. But as this pressure is in proportion to the length of the longer branch of the siphon, it is easy to augment or diminish it by raising or lowering the receiving vessel more or less below the level of the liquid in the aspirating flask. The flow of the liquid from the pleura can also be regulated by means of the stop-cock so as to avoid too sudden diminution of pressure in the pleura. This apparatus enables the surgeon to operate without aids, without interruption, no matter what the quantity of liquid to be evacuated, and with perfect security to the patient. It can also be used for washing out the pleura in cases of purulent pleurisy, by adapting a Y-tube to the trocar extremity, each branch furnished with a stop-cock, to one of which the trocar is adapted, while the other communicates with Potain's washing siphon.

Dr. Ruault has recently employed the above apparatus on two occasions with the best results.

REPORTED MORTALITY FOR THE WEEK ENDING JANUARY 21, 1888.

Deaths reported 2,426: under five years of age 844; principal infectious diseases (small-pox, measles, diphtheria and croup, diarrheal diseases, whooping-cough, erysipelas and fevers) 375, acute lung diseases 496, consumption 548, diphtheria and croup 150, scarlet fever 13, diarrheal diseases 24, typhoid fever 27, malarial fever 15, whooping-cough 13, cerebro-spinal meningitis 12, erysipelas 12, measles seven, puerperal fever four. From diarrheal diseases, New York and Brooklyn seven each, New Orleans 11, Philadelphia five, Boston, Baltimore, District of Columbia and Fall River one each. From malarial fever, Brooklyn six, New York five, New Orleans two, Baltimore and Nashville one each. From whooping-cough, New York six, Baltimore three, Philadelphia, Boston, Pittsburgh and Newton one each. From cerebro-spinal meningitis, New York four, New Orleans and Somerville two each, Worcester, Cambridge and Fall River one each. From erysipelas, New York five, Brooklyn three, District of Columbia two, Boston and Worcester one each. From measles New York four, District of Columbia two, Philadelphia one. From puerperal fever, New York two, Boston and Somerville one each.

In the 28 cities and greater towns of Massachusetts, with an estimated population of 995,619, the total death-rate for the week was 27.53 against 23.87 and 24.91 for the previous two weeks.

In the 28 greater towns of England and Wales with an estimated population of 4,398,273, for the week ending January 7th, the death-rate was 23.8. Deaths reported 4,279: infants under one year of age 885; acute diseases of the respiratory organs (London) — whooping-cough 183, scarlet fever 90, measles 67, fevers 53, diphtheria 42, small-pox (Sheffield 27, Leeds two, Bristol one) 30, diarrhoea 25.

The death-rates ranged from 14.3 in Brighton to 47.3 in Plymouth; Birmingham 19.5; Blackburn 28.5; Bradford 17.7; Hull 19.9; Leeds 23.9; Leicester 24.2; Liverpool 25.1; London 22.8; Manchester 35.6; Nottingham 21.2; Sheffield 26.4; Sunderland 20.6.

In Edinburgh 30.4; Glasgow 27.1; Dublin 38.6.

The meteorological record for the week ending January 21, in Boston, was as follows, according to observations furnished by Sergeant O. B. Cole, of the United States Signal Corps: —

Week ending Saturday, Jan. 21, 1888.	Barom- eter.	Thermometer.			Relative Humidity.			Direction of Wind.			Velocity of Wind.			State of Weather. ¹			Rainfall.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JANUARY 21, 1888, TO JANUARY 27, 1888.

BERTON, H. G., captain and assistant surgeon. Granted leave of absence for one year on S. C. D., to take effect when able to travel. S. O. 19, A. G. O., January 24, 1888.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE UNITED STATES MARINE HOSPITAL SERVICE, FOR THE WEEK ENDING JANUARY 28, 1888.

WHEELER, W. A., passed assistant surgeon. Granted leave of absence for thirty days. January 24, 1888.

WHITE, J. H., passed assistant surgeon. Granted leave of absence for two days. January 26, 1888.

WATKINS, R. B., assistant surgeon. Granted leave of absence for thirty days. January 28, 1888. Resignation accepted to take effect March 15, 1888. January 28, 1888.

VAUGHAN, G. T., assistant surgeon. Appointed an assistant surgeon January 25, 1888, vice A. D. Devan, resigned. Assigned to temporary duty at Marine Hospital, Boston, Mass. January 26, 1888.

SOCIETY NOTICES.

MASSACHUSETTS MEDICAL SOCIETY, SUFFOLK DISTRICT. — THE SECTION FOR CLINICAL MEDICINE, PATHOLOGY AND HYGIENE will meet at 19 Boylston Place, on Wednesday, February 8th, at 7.45 o'clock. Papers: Dr. Henry Jackson, "Fifty Cases of Scarlet Fever." Dr. S. H. Durkin will open the discussion. Dr. Morton Prince, "A Case of Ophthalmoplegia Externa." Drs. O. F. Wadsworth, J. J. Putnam, and P. C. Knapp, will open the discussion.

A. L. MASON, M.D., *Chairman*.

ALBERT N. BLODGETT, M.D., *Secretary*.

GYNÆCOLOGICAL SOCIETY OF BOSTON. — The next meeting of the Society will be held at No. 19 Boylston Place, on Thursday, February 9, 1888, at 4 o'clock, P.M. Paper: "Puerperal Septicæmia, with Report of Case," by Dr. C. W. Stevens.

H. J. HARRIMAN, M.D., *Secretary*.

BOSTON SOCIETY FOR MEDICAL OBSERVATION. — There will be a regular meeting of the Society at the Medical Library, 19 Boylston Place, on Monday evening, February 6, 1888, at 8

o'clock. Readers: Dr. Franklin H. Hooper, "Adenoid Vegetations in Children, with Diagnosis and Treatment." Dr. Clarence J. Blake will speak upon "The Relations of these Growths to Deafness." Dr. E. M. Buckingham, "The Incontinence of Urine."

CHARLES P. STRONG, M.D., *Secretary*.

BOOKS AND PAMPHLETS RECEIVED.

Cooper Medical College, San Francisco. Annual Announcement. Session of 1888.

Annual Report of Morse Dispensary of Cooper Medical College for 1887. San Francisco.

Dystocia from Short or Coiled Funis, and its Treatment. By A. F. A. King, M.D., of Washington, D. C. Reprint. 1887.

Transactions of the American Gynecological Society. Volume 12. For the year 1887. New York: D. Appleton & Co. 1888.

Synopsis of the Second Hundred Cases of Uteral Stricture Treated by Electrolysis, with Cases. By Robert J. Newman, of New York. (Reprint.)

The Climatic Treatment of Phthisis in the State of Colorado. By M. Charteris, M.D., Professor of Therapeutics and Materia Medica, Glasgow University.

Doctor and Patient. By S. Weir Mitchell, M.D., LL.D., President of the College of Physicians of Philadelphia, etc. Philadelphia: J. B. Lippincott Company. 1888.

Operations for Mastoid Disease. By Seth S. Bishop, M.D., Chicago. Surgeon to the Illinois Charitable Eye and Ear Infirmary, to the Illinois Masonic Orphans' Home, etc. Reprint. 1887.

Statistical Report of 5,700 Cases of Ear Diseases, Classified by Age, Sex, Occupation and Disease; Causation. By S. S. Bishop, M.D., Surgeon to the Illinois Charitable Eye and Ear Infirmary, Chicago. Reprint. 1887.

The Galvano Caustery Sound and its Application, Especially in Hypertrophy of the Prostate with Reports of Cases. By Robert Newman, M.D., of New York. Read before the Section of General Surgery of the Ninth International Congress. (Reprint.)

FEVER AND THE USE OF ANTIPYRETICS.¹

BY J. ARTHUR GAGE, A.M., M.D., OF LOWELL, MASS.

How, then, shall we formulate our *theory of fever*? It would be interesting and profitable to consider the different theories that have been advanced, and to show the gradual development of our present belief, but my short time will only permit a brief reference to the most important. The retention theory advanced by Traube, 1863, was long the accepted one, and even now enters into the more perfect theory of to-day in a certain degree. It was as follows: The cause of fever set up a spasm of the v-m-system, with resulting retention of heat and a rise of temperature; the accumulated heat then gave rise to the concurrent symptoms of fever. This was inadequate, and was disproved by the fact that the heat-loss is *greater* in fever, and that there is not a lasting spasm of the vessels; also by the fact that there is a greater heat-formation in fever. In reality, during fever there are great variations in the condition of the vessels of the skin — at one time flushed, at another pale. These irregularities in the rate of heat-discharge in fever may go far to determine the type of the febrile temperature — that is, the configuration of the curve on the temperature-chart, but are incapable of explaining the constantly increased temperature. The proof of increased tissue-metamorphosis led, naturally, to the combustion theory of fever, which may be stated as follows: The increased secretion of CO₂, urea, and the increased heat in fever indicate increased tissue-change, and gives rise to a higher temperature; this, in turn, produces the attendant symptoms. Finding heat-loss inadequate to explain fever, these theorists had grasped the other horn of the dilemma.

The combustion theory was widely accepted, and, to-day, remains as the basis of our conception of the source of fever-heat — but not the mechanism. This theory failed to explain many clinical facts, such as fever following injury to the nervous system, fever attending dentition, and urethral fever. Again, according to some, the amount of urea excreted is not always proportionate to the amount of fever, or rather, temperature, and does not fluctuate with the temperature. The cause of fever is often insignificant (excitement, a cold draught, etc.), and out of all proportion to the resulting fever. Many observers had felt the inadequacy of the theory to explain all cases of fever, and Dr. Ord²⁵ gave voice to this dissatisfaction in a paper in 1885. He offered a new theory, substantially as follows: If you keep a steady heat under a kettle of boiling water, the temperature of the water always remains at 212° F. as long as evaporation goes on. Pour oil on the water, and the heat accumulates; that is, a certain amount of heat disappeared in evaporation. If you let the water boil away, the empty kettle becomes heated to a high point. The amount of heat furnished is always the same; the direction of its energy is alone changed. Now heat may be used up in various ways in the body, as in motion, chemical action, or other energy; and, if any one of these ways is stopped, the heat that went off in the form of energy would be stored up to heat the body itself.

There are in the body two processes, building up

of tissue and disintegration of the same. The latter sets free heat; the former consumes heat or makes it latent. His conclusions are as follows: Combustion starts the fever process, but it is not sufficient to explain all cases. After the process is started the building up of tissue is greatly diminished or stopped, and the heat that would have been rendered latent in this process is set free to run wild and heat the body, represented by the kettle in his experiment. All this, he says, may be under the control of the nervous system. Though this is ingenious and comes from a man of Dr. Ord's preëminent ability, I think it is untenable for the following reasons. Even if the building-up process is arrested the heat-producing power of the food is the only source of the heat he supposes to be made latent in health. This source under fever diet is greatly diminished, and it probably does not go far on the upward course of constructive metabolism, but is burned up early and would then furnish the same amount of heat as albumen anywhere else in the body. The whole source is inadequate to explain the great production of heat, and is less sure than the well-known sources of heat. Secondly, it seems to me a *non-sequiter* to say that, because heat is made latent in a process, the *cessation* of that process should set heat free. It may never have been formed at all. One other observer deserves notice: Dr. Henri Parinaud²⁶ more than ten years ago advanced a theory of fever that is essentially in accord with our present belief. This occurred before the classical experiments of Wood were published, and due credit should be given the author. I shall incorporate his views in the summary. Dr. Wood as late as June, 1887,²⁷ before the association of American Physicians, after recapitulating what we know about heat-loss and heat-formation, sums up as follows: "Fever itself is a disturbance of calorification in which through the influence of the nervous system heat-loss and heat-production are both affected. If there be a fever which is produced independently of the nervous system we have at present no proof of its existence." The cause may be generated outside or inside of the body, but acts either directly or indirectly on the nervous system to give rise to the symptoms classed as fever. Hirtz²⁸ says: "The sudden origin and rapid development and as rapid decline of fever, its sudden disappearance after using antipyretics, its fierce duration in spite of diet, cool baths and spoliations is against a primitive chemical origin, and points to an active agent which lights up and keeps burning the combustion. This agent must be the nervous system." Dr. Broadbent²⁹ concludes that: "If a theory of the febrile process is to be formed it must be based upon a theory of the relation between the nervous system and the processes of nutrition and oxidation, and especially the latter." The consensus of opinion thus points to the nervous system as the controlling agent in fever, and our treatment must be in a measure directed to this system. I must here allude to Dr. Austin Flint's theory advanced in his paper³⁰ before the International Medical Congress. He says that in health we excrete more water than we ingest, and this is formed *de novo* by the union of oxygen and hydrogen with a resulting production of heat.

²⁵ Op. cit., conclusion.²⁶ Boston Med. and Surg. Journal, June 16, 1887, p. 683.²⁷ Diet, de Med. et de Chir., article "Chaleur."²⁸ Quain's Dict. of Medicine.²⁹ Medical News, Sept. 10, 1887, p. 281.¹ Concluded from page 116.² Brit. Med. Jour., October 24, 1885, p. 782.

In fever this formation of water is diminished, and its elimination by the skin also decreased; in its place the tissues are burned up to supply heat. I cannot see that he adds anything to our knowledge of the source of heat-formation in fever; possibly the lessened transpiration may explain why there is less heat lost by the skin. At any rate his claim to have established a new theory of fever seems hardly proven, and I find that Dr. Davis, President of the Congress, in a recent editorial takes exception to his views. I must also mention two very interesting papers by Macalister³¹ and McClagan³². The former calls attention to the important part heat-retention plays in fever, and the latter applies the theory to disease. They are very suggestive papers, though somewhat problematical, and are worthy of study.

What then is the picture of fever that we must form for ourselves from the data we have? A man is taken with a chill followed by high temperature, increase of the CO_2 and urea excreted, and disturbance of the various functions of the body with wasting of the tissues. These symptoms may be due to traumatism, to inflammation, to entrance into the body of chemical or living poisons, or to some disease or injury of the nervous system. What has happened to set up these changes? If we take such an injury to the nervous system as a hæmorrhage, it is evident that the only way in which such a condition can give rise to an increase of heat-formation and tissue-metamorphosis is through its action on the blood or nerves, for these alone pervade and influence all tissues. In the absence of inflammation it is inconceivable how any influence could be exerted through the blood, and we are left to explain the action by means of the nervous system. The following explanation is possible in the light of our present knowledge. The hæmorrhage acts by paralyzing the inhibitory centre or its efferent nerves, thus giving free rein to the process of combustion, just as you would increase the heart beat by cutting the vagus. At the same time the v-m-system is relaxed, and more heat is given off; but the relations between the two functions is not maintained as in health, and the temperature rises.

If we consider the irritative fevers, as urethral fever, fever following dentition, or a nail in the foot, or a slight burn on the body, we are again compelled to explain the sequence of symptoms by the agency of the nervous system (I am aware that urethral fever is attributed to the entrance of germs, but the history is certainly inconsistent with what we know of the action of micro-organisms in other fevers). In this class of fevers, the cause must act not directly on the nerve-centres, but first on their afferent nerves, and, through them, the centres controlling heat. This has an analogy in health, where the effect of cold or heat on the temperature-nerves of the skin increases or diminishes heat-formation. The paroxysms of intermittent fever are best explained on the ground that the poison affects the nervous system primarily, since it is not easily conceivable how a poison acting merely in a chemical manner on the tissues could be periodic in its phenomena. Sunstroke is also best explained by supposing the heat to *unnerve* the heat-centres. It cannot be explained merely on the physical ground of exposure to great heat, for men endure much greater heat without a similar result. The hyperpyrexia occurring

in cases of rheumatism, when the temperature reaches 110°F , with alarming nervous symptoms, is capable, in accordance with our theory, of an explanation that is highly suggestive as regards the rôle the nervous system plays in fever. This condition does not occur in all cases of rheumatism, and, therefore, can hardly be due to the usual cause. It is explained as follows: In this disease there is great heat-formation and great heat-loss (shown by the profuse sweating), while the temperature does not reach an uncommon height because the nerve-centres control it. The unusual strain on the heat-centres in doing this may, however, exhaust them, and the control is lost. Heat-formation and heat-loss are no longer correlated, and the temperature rises to a dangerous height with the advent of prominent nervous symptoms. If we look at the zymotic diseases, where the agent is now thought to be a living micro-organism, the explanation of their action is not so easy. They may act locally on the tissues (as McClagan claims) through the blood, and, no doubt, they do so in the destruction of red blood-corpuscles, and in the effects on the skin in the exanthemata, *et cetera*. Whether this local action increases heat-formation without the intervention of the nervous system, we cannot yet say. It is known that these germs produce chemical products in the body, known as ptomaines, and Dr. Wood believes that these act on the nervous system to produce fever. If the germs act in purely a local manner, we certainly should not expect the long period of incubation before the fever appears. On the other hand, many purely local lesions cause general fever, and it seems most probable that they accomplish this by some channel of communication common to themselves and the tissues generally. These are a few examples of the application of our theory to disease, and many more might be adduced. But, however we explain the cause, we must not forget the essential fact that, once started, the fever process is under the control of the nervous system, and, if we can act upon this nervous mechanism, we can influence the tissue processes, though we do not affect the poison that causes them. This may explain the reason why certain drugs do not shorten the duration of a disease, though they modify its essential phenomena.

What, then, is the *rationale* of the use of antipyretics in fever? They may act in two ways: (1) By simply reducing high temperature. (2) By removing or counteracting the cause. They may reduce the body-heat either by increasing heat-dissipation or by diminishing heat-formation; but, in order that their employment for this purpose may be justified, we must first show that high temperature in itself is injurious. Dr. Wood³³ has done this for the nervous system in a series of experiments, and I think his conclusions are sound, in spite of Dr. McClagan's criticisms. T. Lauder Brunton³⁴ has also shown that heat acts disastrously on the heart. It is possible, also, that many parenchymatous changes of organs which follow fever, and make recovery so slow, are due to the effects of excessive heat. We are justified, then, in giving drugs for the reduction of temperature alone if they have no injurious counter-effects, for we thereby save the nervous system and the tissues generally from destruction, though we may not modify the course of disease.

³¹ Lancet, March 12, 1887, p. 507 et seq.

³² Lancet, Feb. 26, 1887, p. 114, Nos. IX-XIV.

³³ Op. cit., Chap. I.

³⁴ Reported by Wood.

The most common agents for the reduction of temperature are baths, veratrum, aconite, quinia, and antipyrine and its congeners. It is a well-recognized clinical fact that these agents reduce temperature by acting on the v.m. system to relax the cutaneous vessels and to cause sweating, and a discussion of their action upon heat-loss need not detain us. Do they affect heat-formation? It was one of my early impressions as a hospital student that the effect of sponge-baths in reducing temperature could not be satisfactorily explained on the ground that they acted merely by conduction and evaporation; nor did the sweating they sometimes induced solve the difficulty, for cause and effect were often out of proportion. I was thus left with the rather indefinite impression that they might modify the fever process. Now we all know the tonic effect of a cold shower-bath upon a healthy man — why should not the bath in fever act upon the temperature-nerves of the skin to stimulate the inhibitory heat-centre, and to diminish heat-formation? Why should not quinia and antipyrine act by stimulating this centre directly, and so strike at the very root of fever? Dr. Arduin³⁵ claims that this is true, at least, for antipyrine, and recent experiments at the Pennsylvania Hospital corroborate this opinion. If these conclusions shall be substantiated, we shall have a sure foundation upon which to base our use of antipyretics. Can these drugs affect the cause of disease? Our answer must be only provisional. In nervous pyrexias, where the fever originates in a disturbance of the nerve-centres, antipyretics may act directly upon these centres to quell the disturbance.

In diseases where the cause is a poison, they may have some action as antiseptics, and Dr. Williams³⁶ calls attention to the fact that aniline, closely allied to antifebrine, is a good germicide, particularly for the tubercle-bacillus. But, whatever the theory of their action, the clinical fact remains that they reduce high temperature, and will thus save the patient from many bad symptoms. Even though they may not shorten the course of the disease (and there is some little testimony that they do this), they will put the patient in the best possible condition to rally after the disease has run its course. This opinion is concurred in by careful observers who have watched the effect of antipyretics in an extensive hospital practice. Drs. Shattuck³⁷ and Mason,³⁸ of the Boston City Hospital, Dr. Minot,³⁹ of the Massachusetts General Hospital, Dr. Wood, of Philadelphia, and many others at the meeting of the Association of American Physicians, report good results from the use of antipyretics. If we compare the different drugs to decide which is the better, we shall see that there is a choice. Veratrum and aconite are ruled out, on account of their depressing action upon the heart. Quinia, although efficient, has many disagreeable effects. Of the more recently-discovered antipyretics, antifebrine stands at present at the head. It is efficient in small doses, 3-5 gr., and is not followed by the depression that accompanied many of the earlier drugs. It is also cheap. It has the one disadvantage of being insoluble in water, but can be given in alcohol or syrup. I should like to discuss its use in different diseases, and speak of some

of the results, but I have already over-stepped the limits of my paper. I could also wish to offer you some practical suggestions as to the employment of antipyretics; but if I have given you some food for thought, some theory on which we can safely and rationally base our practice, I shall feel repaid for my labor.

CASES OF NERVE STRETCHING, NERVE SECTION AND NERVE SUTURE, AND OPERATIONS TO RELIEVE PRESSURE ON NERVE TRUNKS.¹

BY M. H. RICHARDSON, M.D.
Surgeon to the Massachusetts General and Corney Hospitals. Assistant Professor of Anatomy, Harvard Medical School.

IN October, 1886, I presented a paper upon this subject to this Society² with report of several cases. I have been able to follow up several of these cases, and it may be of interest to give the present condition of those I have been able to see recently.

CASE I. George Donaboe. Case of suture of the musculo-spiral. This man met with a severe injury to the right upper extremity from the caving in of a sand bank. He sustained a fracture of the right clavicle with a good deal of displacement. He has been a good deal disabled in the arm from pain and stiffness in the acromial region. Up to the time of the accident, the usefulness of the upper and forearm and hand had constantly improved, and he considered himself as good as ever.

CASE II. Mary Quinn. This case of secondary suture of the ulnar nerve was seen by me often during 1887. The hand was useful and the muscles supplied the ulnar were under control to a certain extent, as shown by the voluntary action of the interossei. The interesting point in this case was the long-continued pain in the cicatrix extending into the finger. This suture had been made with fine silk. One at least of these sutures had been discharged from the wound, and during this process there was considerable local inflammation. This experience led me to use fine catgut instead of silk in all subsequent sutures, as in the musculo-spiral case.

CASE III. Infra-orbital neuralgia of epileptiform character. One year later there was a slight return. Dr. Putnam relieved this by the use of rhigolene, and no second operation was done.

CASE IV. Bixby. Case of inferior dental neuralgia. This returned at the end of a year and was very violent and paroxysmal in character.

CASE V. Stretching of the spinal accessory for spasmodic wry-neck. No operation has been done subsequently.

I have been informed by Dr. W. N. Bullard, who had the charge of this man after my term of service had expired, that he was considerably benefited by the operation, and that the twitching was very materially permanently lessened. There was not, however, a complete cessation of the spasmodic movements of the head. He was able to be of considerable service about the hospital and became night nurse in the male ward.

The following cases have come under my observation since my last report. The operation of nerve suture has been substantially the same as in previous cases with the substitution of cat-gut for silk. It is

unfortunate that the final result in these cases is so uncertain. They were all under observation long enough for me to determine whether any of the accidents sometimes seen in this operation were present or not, and to see slight return of both motor and sensory function. It is possible that a complete restoration has followed, but I have not been able to see or hear from the cases since.

CASES OF NERVE STRETCHING.

CASE I. November 11, 1886. P. J. O., aged forty-eight.⁵ Four years ago this woman had severe neuralgic pains in the right side. These lasted for about one year, and then got better. Two years ago the trouble came back on the other side. The marked peculiarity in this case was the severe and uncontrollable contractions of the abdominal muscles on the left side. Every few moments the muscles on that side would contract violently and painfully, producing pleurosthotonos. These attacks were much more pronounced when attention was called to them. Electricity and plaster jackets had been tried without success. Patient couldn't walk. She was very much bent towards the affected side, and had an almost constant twitching of the affected muscle with severe pain. After consultation with Dr. Putnam it was thought best to stretch the lower intercostal nerves.

November 23d. An incision five or six inches in length was made parallel to and an inch below the lower border of the ribs on the left side. All the nerves in this incision were divided or stretched. Bichloride irrigation, silk sutures and antiseptic dressings. The wound was healed two weeks after the operation. There was no marked change for the better although the frequency of the attacks seemed diminished.

December 26th, a plaster jacket was applied. She has not been seen or heard from since. This operation was not a success. From whatever cause this spasmodic contraction of the muscles proceeded, it is clear to my mind that stretching of the motor nerves is not sure enough of producing any lasting benefit to warrant so severe an operation. It is necessary to make a very long and deep incision to find the nerves, and if any number of them are to be found the cut will have to be a very long one. To accomplish any decided results I am sure that these nerves must be divided, and a sufficient number to produce a very decided paralyzing effect. There is no danger of a permanent paralysis because the nerve supply to the abdominal muscles is so extensive. It is questionable whether in a similar case I should advise nerve-section. It was very probable that the trouble in this case was of central origin, and not in the nerve trunks themselves. In such a condition of things I do not see that anything short of complete and permanent paralysis can be effectual. By the incision along the lower border of the ribs a larger number of intercostal nerves can be reached than by any other one cut of the same length.

To paralyze the whole of the muscles it is necessary of course to reach the ileo-inguinal and ileo-hypogastric nerves as well as the intercostals. To divide them all makes the operation very extensive, and, in my opinion, it is to be recommended only in extreme cases, like the above. In such a case I should now cut the intercostals first, and later the ileo-inguinal and hypogastric branches.

CASE II. Peter Tierney,⁴ aged thirty-six, coal heaver. Entered the Massachusetts General Hospital, August 26, 1887. General health good. No history of rheumatism or syphilis. Eight months before admission, after unusual exposure to cold and wet in loading vessels at the wharves, patient began to suffer pain in back of thigh. Pain increased, and in a week he was obliged to give up work. Since that time he has suffered constantly with pain in the course of the sciatic nerve. Had been under treatment by Dr. Putnam in the nervous room of Out-patient Department with massage, cautery, etc., without much benefit. Complaints of severe and constant pain in the back of the left thigh along the course of the sciatic and in back of knee and calf. Pain especially intense opposite the great trochanter and at middle of thigh. Great tenderness to pressure along whole course of nerve. Muscles of left thigh and calf flabby, and an inch less in circumference than in right. Has frequent tingling sensations in left foot.

August 27th. Considerable pain. Lies in bed with leg flexed and everted. Seen by Dr. Putnam who advised deep injections of chloroform. In the afternoon needle of hypodermic syringe inserted deeply between trochanter and ischial tuberosity and seven minims of chloroform injected.

August 28th. Pain in leg unrelieved. Anxious for anything to give relief, and willingly consents to have nerve stretched.

August 30th. Operation under ether. An incision two and a half inches in length was made in the long axis of the thigh commencing at the lower edge of the gluteus maximus muscle half-way between the tuberosity of the ischium and the great trochanter. The fascia was divided and the nerve readily exposed and hooked out of the wound by the finger. It was then forcibly drawn upon two or three times to the extent of raising the limb. A soluble drainage tube was inserted, and the wound closed with a continuous cat-gut suture. There was nothing abnormal in the appearance of the nerve. The next day there was relief from the pain in the leg, although there was some pain in the cut. No anesthesia or motor paralysis. Two days after operation complained of pain in the same locality as before operation, but not so intense.

September 6th. A week after operation the wound was dressed for the first time. The tube and the stitches had disappeared. First intention. Pain the same as before.

October 1st. The pain being still severe and unrelieved he was etherized, and extension on the nerve made by strong flexion of the thigh on the abdomen with the leg and foot extended. Recovered from ether well, but there was no less pain in the leg.

Discharged from the hospital on the 5th, to return in three weeks. Has not been seen since.

This case was not benefited in the last by either operation, and it must be considered a complete failure.

CASE III. August 21, 1887. James Brady,⁶ laborer, aged fifty. Fifteen years ago patient received a blow over left buttock with a pick. Three months after began to suffer pain in the back of thigh and front of the leg. This pain has continued but with little severity and frequent intermissions ever since. Within six months pain has been more severe and constant. Under treatment in the out-patient room

⁵ Vol. CCXXIV, p. 212, Mass. Gen. Hosp. Records.

⁴ Vol. CCXXXII, p. 122, Mass. Gen. Hosp. Records.

⁶ Vol. CCXXXII, p. 181, Mass. Gen. Hosp. Records.

for some time without benefit, and referred to the house to have the nerve stretched.

August 23d. Under ether the limb was forcibly extended so as to put the nerve on the stretch.

August 24th. Pain somewhat relieved. Patient examined by Dr. Putnam who advised against operation. Discharged. Slightly benefited.

CASES OF NERVE SECTION FOR NEURALGIA.

CASE IV. October 14, 1887. S. P. B.⁶ The case of this patient was reported by me in a paper read before this society October 11, 1886, and published in the JOURNAL October 21, 1886. Has had complete relief for one year. A few weeks ago the pain returned worse than ever. No assignable cause. He was put upon salicylate of soda in twenty-grain doses, three times a day. Dr. Putnam also applied rhigolene. There was some benefit from this treatment. The pain recurred every morning about six o'clock with a less severe paroxysm towards night. Quinine taken at 4 A.M. relieved the pain for three or four days, and he was at his request discharged to continue the treatment at home.

November 4, 1887. Re-enters for operation, with pain as severe as ever.

November 7th. Operation. An incision was made over the ascending ramus of the jaw about two inches in length parallel and between the fibres of the masseter. The branches of the facial nerves were carefully avoided. On scraping back the periosteum at the same place where the jaw had been trephined the year before the surface of the bone was found to be perfectly smooth, and without the slightest sign of the previous operation. The chisel was applied along the course of the inferior dental canal. But neither canal nor nerve could be found. The whole region of the canal was gouged out as before. The mental foramen was next found after thrusting a pin into it. The nerve was found emerging from the foramen enormously enlarged. Its branches were collected together, and pulled out of the canal, and also from the tissues to which it was distributed. The foramen was chiselled out and the nerve destroyed a considerable distance. Wounds closed with silk and drained in the usual manner. The next day there was very severe pain. Wound was found sealed, and the tube was removed. Pain continued very severe, and paroxysmal in character. Ten days after operation the pain began to be less. Wounds healed by first intention. Pain gradually disappeared, and he was discharged the 19th.

This case is interesting from its continued recurrence, and from the evident fact that the pain was due to collateral trunks. The size of the branches emerging from the mental foramen was very evidently much greater than is ever seen in the normal nerve. Another interesting fact was the entire obliteration of the canal at the seat of the former operation, showing, of course, that there had been no regeneration of the trunk of the nerve in the way usually supposed.

January 6th, I saw the following case in consultation with Dr. Walton. P. S., from Connecticut, foreman of a machine shop. Six weeks ago while working on a lathe the bar of steel on which he was at work flew from the lathe and struck him over the right eye. After recovery from the immediate effects of the injury, he continued to experience pecu-

liar sensations on the right side of his head with more or less dull pain extending from the right supra-orbital region to the top of the head, and sometimes in the occipital region of that side. He found difficulty in draughting on account of sensations in his head which he described as not exactly a pain, but as a confused sensation sometimes accompanied by pricking and numbness. While sitting perfectly quiet there was no special pain anywhere. There is a broad linear scar extending obliquely upwards and forwards from the outer angle of the orbit about three-quarters of an inch in length. Slight loss of substance. Not adherent to the underlying parts. The lightest touch behind this scar outwards over the temporal region caused tingling sensations to run upwards over the entire region supplied by the supra-orbital nerve. Deep pressure over the nerve or its branches caused no sensitiveness or pain. A light touch inside the scar produced no symptoms whatever. There was no tenderness over the supra-orbital notch. The patient complained of a numb sensation in the region supplied by the supra-orbital nerve, but the physical examination showed no definite loss of sensation. Dr. Walton was of the opinion that the lateral branches of the supra-orbital nerve were involved in the cicatrix and advised excision of the scar.

January 7th, I excised the scar, and found a large branch of the supra-orbital running directly into it. I caught it with strong forceps, and twisted it out of the tissues. Wound closed with silk. January 8th, first intention. Complete cessation of sensitiveness and sensations of discomfort.

NERVE SECTION FOR SPASMODIC WRY-NECK.

CASE I. October 17, 1887. Mrs. M. A. R.⁵ aged forty-eight. A very nervous and spare woman who for four years had suffered from contraction of the right sterno-mastoid and trapezius muscles. This was not constant at first but very painful. For a long time the spasm was tonic and clonic with more or less constant pain. The head was drawn to the right and rotated slightly. She had been under the care of Dr. Putnam with whom I had seen her in consultation. She had tried many remedies without effect. Electricity and various apparatus had also been used without success. As a last measure division of the right spinal accessory nerve was advised by Dr. Putnam and myself, and she was sent to the hospital for that purpose.

At the time of entrance it was found that the right sterno-mastoid was rigid, and permanently contracted. When fully relaxed the head could be brought to an erect position, but no farther than that. She could hold the head erect herself, but on relaxing her efforts it would be drawn toward the right shoulder and rotated towards the left.

October 28th. Under ether an incision *one inch* long was made over the nerve along the anterior border of the right sterno-mastoid muscle. The dissection was carried directly backwards towards the vertebrae. The nerve was found very easily, and an inch of it removed. The diagnosis was confirmed by the electric current before the nerve was divided. The wound was closed with silk and iodoform gauze applied. Bichloride solution irrigation during the operation.

Two days later the stitches were removed. The

⁶ Vol. CCXXXIV, p. 13, Mass. Gen. Hosp. Records.

⁵ Vol. CCXXX, p. 229, Mass. Gen. Hosp. Records.

right sterno-mastoid was soft and flexible. The head was erect and there was no pain. The head was carried towards the right shoulder at times from force of habit.

A few weeks later she re-entered for the purpose of having the right trapezius divided. It had been found since the operation that the anterior fibres of this muscle were somewhat contracted, and that it was impossible to bring the head to more than the erect position on account of this shortening, and the previous long-continued contraction. After the division of the spinal-accessory nerve the trapezius together with the sterno-mastoid had become much relaxed, and had ceased their spasmodic contraction. The sterno-mastoid was easily stretched to allow free movement of the head, but the trapezius would not allow this motion. The other muscles on that side seemed also to be contracted, especially the scalenus medius. After careful examination it was thought impracticable to relieve the contraction by division of the trapezius alone, and a general division of the muscles on that side too severe an operation to be thought of, considering the slight discomfort then present. At the present time she is very comfortable, and will have an apparatus to stretch the affected muscles. An interesting point in this case is the question of collateral nerve supply to the sterno-mastoid. The main supply is from the spinal accessory, but it also has some filaments from the cervical plexus. The immediate effect of division of the spinal accessory is to relax the muscle, to weaken it but not to paralyse it completely. It is a very much more satisfactory operation than stretching, and I believe it to be even safer. The case of stretching reported last year was not permanently benefited. The fear of causing complete paralysis of the muscle is groundless, and the effect on the muscle is just what is desired. As to the matter of incision, it seems to me that the cut I have described along the anterior border of the sterno-mastoid is much better than any other. The nerve proceeds outwards from the jugular foramen, and enters the muscle obliquely about an inch and a half below the mastoid process. It can be found at the bottom of an incision an inch long made at this point. An aid to finding it is to scratch with a director the tissues at the bottom of the wound as you go along, by which the nerve is irritated into causing a contraction of the muscle. It is also large enough to be left in a thin person. If the mastoid alone is to be affected it might be better to seek the mastoid portion by an incision through the centre of the muscle parallel to the fibres. The part of the trapezius supplied by this nerve is so small, however, that I think it is just as well to divide the main trunk.

NERVE SECTION AND SUTURE.

CASE I. AUGUST 25, 1887. Patrick Treenny,^{*} aged thirty-two, laborer. For six or seven years has had a tumor near the elbow which has been very tender to the touch, and the seat of severe pain. Also another on the back near the left scapula. A small bunch is seen just behind and above the internal condyle of right humerus, the size of a cherry. The pain runs down into the hand.

August 26th. Operation. An incision was made along the course of the ulnar nerve just over tumor. A tumor was found encapsulated in the nerve trunk

itself, the fibres of which could be seen spreading over and through it. The capsule of nerve and tumor was found to be the same and continuous. As it was impossible to dissect the tumor from the nerve, the nerve itself was cut both above and below. By extending the arm and relaxing the nerve, and by stretching it, the ends were readily approximated and the sheaths stitched with cat-gut, making a very perfect joint. The wound was closed with a continuous cat-gut stitch. Antiseptic dressings. The arm was placed extended upon a splint which reached almost to the axilla. For a few days after the operation there was a good deal of pain in the wound, and numbness in the arm and hand. Paralysis of sensation along the course of the ulnar nerve.

September 5th, the splint was removed from the arm, and the wound found to be solid. The same day the tumor over the scapula was dissected out and found not to be connected with any nerve large enough to be seen. Five days later the stitches were removed. There seemed to be at this time a certain amount of separation of the fingers possible, especially in the abduction of the index finger. Hand still decidedly weaker than the opposite.

September 14th. Discharged to the Out-patient Department. Examined by Dr. Walton, some weeks later. The muscles supplied by the ulnar nerve were atrophied showing re-action of degeneration.

In this case the principal trouble was excessive and disabling pain, especially in the tumor of the arm. This was completely relieved by the operation. The man has been lost sight of, and it is a question how much restoration of the motor function of the nerve has taken place. It may be said, however, that none of the accidents or complications of nerve suture were present in this case, for he was perfectly free from symptoms of neuritis, and from that disturbance of the nervous system sometimes seen after nerve section and suture.

Dr. Putnam's report of the microscopic examination of the tumor: "Tumor attached to the ulnar nerve. Size of a small walnut. The ulnar nerve in passing over it is spread out so as to cover a space one and a half centimetres wide. Examination of the nerve fibres shows some of them to be healthy, others in a state of commencing degeneration. On examination the tumor proves to be a sarcoma. It is made up of a mass of fibres, small cells with elongated processes and round cells. Here and there a small mass of fat cells is to be seen. The cells are readily stained with hæmatoxylin and on treatment with acetic acid are seen to contain a distinct nucleus. The intervening fibrous substance is not arranged in any characteristic manner."

CASE II. July 6, 1887. William Clive,^{*} brake man, aged twenty-two. Caught his wrist between the bunters while switching cars. Had a cut over the inner and posterior surface of the wrist just above the styloid process of the ulna. The edges were ragged and the muscles torn and bruised. Ulnar nerve divided as well as the tendon of the flexor carpi ulnaris. Under ether the ends of the nerve were found and sutured with fine cat-gut. The tendon ends were also sewed together with the same. Wound united with silk, and iodoform gauze dressings applied. The arm was laid in a tin splint so as to keep wrist flexed. Internal angular splint.

The next day had severe pain in hand and arm.

^{*} Vol. CCXXXII, p. 189, Mass. Gen. Hosp. Records.

^{*} Vol. CCXXXII, p. 98, Mass. Gen. Hosp. Records.

The pain was along the course of the ulnar nerve, and in the little finger. Temperature was elevated the second day after the operation. Wrist was found to be swollen and very tender. All stitches were removed. A few drops of pus were squeezed out. Dry dressings.

July 9th. Phenyle poultice. Wound suppurating.

July 15. Wound granulating, and in good condition. Discharged to the out-patient department.

I have not been able to see this man since he left the hospital. He has been at his work as freight brakeman on the Fitchburg Railroad ever since, and I understand that he is able to attend to all the duties of that position.

OPERATIONS TO RELIEVE PAIN FROM PRESSURE.

CASE I. April 13, 1887. J. L.,¹⁰ mill operative, aged twenty-three. Father had sciatic rheumatism. One sister had cerebro-spinal meningitis. Always strong and well. Four years ago turned her left ankle. Five months later began to have constant pain limited to a small area on the outer side of the left leg about the middle of the calf. A sharp lancinating pain extending along the course of the musculo-cutaneous nerve. This spot was also very sensitive to pressure. Pain was increased by exercise. Left leg occasionally swollen. Had been treated with rubber bandage, blistered eleven times, actual cautery two years ago, and electricity. No relief. Had been wearing a rubber stocking for some time. Had a scar on the outer side of the calf at about the junction of middle and upper third of the leg about the size of a vaccination mark, caused by the cautery. This is the seat of the pain and is very tender. Very slight tenderness over a small area about it. Was given salicylate of soda, ten grains three times a day.

April 20th. No relief. Operation by Dr. Beach under ether. The scar left by the cautery dissected out. Dissection carried down to the fascia. No nerve fibres discovered. Closed by silk sutures and antiseptic dressings.

April 22d. Some tenderness over the incision. None of the lancinating pain. Stitches removed.

April 26th. Healed by first intention. No pain, and scarcely any tenderness. Discharged.

July 28th. Re-entered. Was free from pain for about three weeks after discharge. Pain and tenderness returned in former situation and of greater severity than before.

July 30th. Operation. An incision was made in the line of the scar of the former operation extending an inch above and below it. The cicatrix of the former operation was removed by an elliptical cut. Aponeurosis covering the muscles was exposed and nerves carefully sought. No nerve filaments could be found whatever. There was no evidence that the cicatrix had involved any considerable nerve branch. The fascia was then divided by a crucial incision, and the musculo-cutaneous nerve sought in the space between the extensor communis digitorum and the peroneus longus. After quite prolonged search among the fibres of these muscles which had a peculiar fatty-infiltrated appearance at this point, a tumor was found into which the nerve apparently went. The tumor was removed without difficulty. It was encapsulated. What appeared to be the nerve was a fibrous band from the intermuscular septum which expanded and

lost itself in the tumor. The musculo-cutaneous nerve was found in such a position that it was evidently compressed between the fibula and the tumor. The gross appearance of the tumor was that of a melanotic sarcoma. Unfortunately it was lost and no microscopic examination was made.

August 5th. Stitches out. No pain.

August 10th. Discharged well. No pain.

November, 1887. She wrote that there was a return of pain or rather discomfort. Was advised to return for examination.

This case illustrates the importance of seeking a cause for a persistent local pain. There was not the slightest evidence of the existence of a tumor by physical examination. Yet there is no doubt that she had been suffering not only from long-continued pain, but from repeated therapeutic measures. I think it may be said as a rule that persistent pain localized in the course of a nerve which has not yielded to a long-continued course of counter-irritation and internal remedies, makes it the duty of the surgeon to cut down and see if there is not some cause that can be removed as easily as this was. Moreover, if there is a tumor pressing on the nerve the sooner it is removed the better, especially if it proves to be, what this probably was, malignant. The recurrence of pain in this case leads me to think that there is a return of the growth, and I have advised her to come immediately for examination and operation.

CASE II. Mary A. P.,¹¹ aged twenty-three. Fourteen years before entrance she fell and injured the right elbow. Then arm was put on a splint and kept there six weeks. Never had any trouble in it till recently though the elbow-joint was a little stiff. Four or five years ago the elbow began to pain her. She first noticed pain in bending the arm to a right angle. That has steadily increased till at the time of the operation the arm was almost entirely disabled, and she wore it in a sling. On examination of the arm a small bony growth was perceived at the elbow joint, situated just to the outside of the tendon of the biceps. The pain as described followed the course of the external cutaneous nerve. There was very little tenderness in the bunch itself, but at a certain point in flexion and extension there was a sharp twinging pain like that of the crazy bone. A diagnosis of pressure on the external cutaneous nerve was made. On cutting down to the bony projection the nerve was found between it and the biceps tendon in so close relation that every time the biceps was flexed or extended the nerve was sharply compressed between the two. The growth was chiselled off smooth from the lower part of the humerus to which it was attached and the wound closed as usual. Corrosive sublimate irrigation and iodoform dressings. Healing was by first intention. The pain was relieved entirely and has never returned.

— Our esteemed contemporary, the *Medical Record*, reports in one and the same issue two cases which appeal pretty strongly to the wonder element — the one of a man who has just died in Constantinople at the age of 115 years, "a personal friend of Marat, Danton and Robespierre"; the other a young lady of Japan, aged twelve years, five months, whose height is eight feet, and her weight 270 pounds.

CASES OF FEBRILE DELIRIUM TREMENS.¹

BY WILLIAM S. HULLARD, M.D.,
Visiting Physician Carney Hospital, Instructor in the Boston Poly-
clinic.

THE existence of certain specially dangerous and hyperacute forms of delirium tremens has been known and recognized by many writers since the days of Magnus Huss, but the first distinct description of this class of cases in which an attempt at their differentiation from the ordinary type was made, seems to have been that of Delasiauve, of his so-called superacute form (*forme suraigue*) in 1852. In his cases, however, the distinctive symptom of fever was absent, and it was left for Magnan, in 1873 and 1874, to describe as a distinct variety, his cases of febrile delirium tremens.

Although the cases which I am about to report do not agree in all respects with those related by him, I have ventured to make use of the title of febrile delirium tremens for them also. One of the predominant symptoms, perhaps we may even say their most striking characteristic, was the presence of fever, and in many points they closely resemble the cases of Magnan. Moreover, there can be little doubt that the different varieties of delirium tremens shade imperceptibly into each other and that they are all acute manifestations of chronic alcoholism modified in their symptoms by the constitution of the patient, his condition at the time, the existing complications and various other attending circumstances.

The presence, however, of so important a symptom as fever, affords, in our opinion, a sufficient ground for placing those cases in which it exists to any marked degree, in a separate category from the ordinary simple febrile cases. Since, after as thorough an examination as possible of the voluminous literature of delirium tremens, we have found no carefully reported cases of this character, since those of Magnan, we feel justified in bringing these to the notice of the Society, more especially as we believe that there are certain considerations connected with them of considerable importance both to the specialist and perhaps even more to the general practitioner.

The first case which I shall present, is as follows:

On the 24th of September, 188-, the patient, a professional man, aged thirty-two, entered the Hospital under my charge. The following history was obtained from his relatives and friends, partly at the time and in part later.

Family history entirely negative. When about fifteen or sixteen years old, patient had some mental trouble and was sent to the McLean Asylum for a time. He recovered from this perfectly, was afterwards healthy and an exceptionally bright and intelligent student. For several years previous to entrance he had been addicted to the use of alcohol in excess and about four years previously was sent as a patient to the City Hospital, suffering from delirium tremens. Since then he had been under the influence of alcohol much of the time, but his family state that for the four weeks preceding admission to the Hospital, he has had only one bottle of ale per diem, and nothing else. For some time he has been thought to have been a little "queer," but this was first noticed by the family four weeks ago, when he came to live

with them. It was then perceived that at times he did not seem to realize where he was, and he would frequently make remarks which had no apparent connection with the conversation or with his surroundings at the time. He had distinct hallucinations of sight and hearing and spoke, for example, of hearing his mother sing, she having died some time previously. He appears at this time to have used some morphine, but not any large amount. These symptoms gradually increased in severity, and he was brought to the Hospital on their account.

When first seen by me on the day after entrance, he was sitting up, recognized the people whom he had previously known and talked rationally during the visit, though he did not know where he was and was easily confused. He was markedly weak and languid, complained of no pain, but of discomfort in his head. Face flushed; lips dry and cracked. Pulse 120, weak.

R. Ammon. Carbon. grs. v. t. i. d.

On the day following (September 26th), the patient was decidedly worse. He was almost unable to recognize friends or to answer questions, and was confined to bed, being too weak to stand. The bowels were somewhat constipated; there was no headache or vomiting.

September 27th. In bed. Pulse stronger, 110. Has distinct delusions of sight and hearing. Talks steadily to imaginary persons. Talks to physician as though he were some one else. Physical examination gives negative results.

September 28th. Was to-day ordered whiskey $\frac{zss.}{ss.}$ on account of weakness of pulse. Otherwise has had no alcoholic stimulant since entrance.

September 29th. Patient is now in a distinctly typhoidal condition, face much flushed, tongue, which when first seen, had a thick white coat, has now a dry yellow coating and is cracked and parched. Lips covered with sores. Pupils alike, normal, react fairly. Temperature has been 99° in the mornings and rose in the evenings to about 102°. Pulse 120, a little stronger. Bowels moved freely yesterday. Nothing abnormal detected in the urine.

He is now in a state of muttering delirium, plucks constantly at the bed-clothes, yet he recognizes people, at least partially, when asked who they are. Has been so restless at night that he had to be held in bed. Takes his food (milk) well.

Patient was seen to-day by Dr. Jelly in consultation, and a provisional diagnosis of subacute cerebral meningitis was suggested. An ice-bag was ordered to the head, and iodide of potassium (gr. xv, t. i. d.), and bromide of potassium (gr. xx, t. i. d.), prescribed. The carbonate of ammonium was omitted, but renewed the next day.

September 30th. Found patient this morning in a semi-comatose condition, after a somewhat restless night. He could be roused only with considerable difficulty and then recognized physician. The power of recognition varies according to his condition at the moment; on the 27th he did not recognize his brother. Pulse more feeble, 120. Temperature morning and evening normal. Pupils both dilated, right smaller than left; both react to light. Later in the day the pulse became more rapid, 128, scarcely perceptible at the wrist, and ammonia was given subcutaneously. Retention of urine, so that catheter was required.

After this, through change of service, the patient

¹ This paper was read in substance at a meeting of the Medico-Psychological Society on the 19th of May, 1887, but the title, according to a proviso made at the time, has been changed, and certain additions and modifications have been made.

passed under the care of Dr. G. M. Garland, to whose courtesy I am indebted for permission to make use of the Hospital records relating to this patient while under his charge.

October 1st. Temperature this morning 99°; pulse regular, 128, soft and feeble. Complains a little of acute lancinating pain in the head. Imagines that people are pursuing him, and tries to run away from them. Mutters a good deal and talks thickly. Knew the physician and called him by name, then became confused. Fumbling of the bed-clothes. Urine passed involuntarily. Tongue very red, dry in the centre, secretions of mouth thick and adherent to gums. Conjunctivæ pale, pupils equally dilated, no photophobia, convergence good, hearing perfect, no sensitiveness to sounds. Cheeks and superciliary regions congested. Tache cérébrale slightly marked.

Was ordered carbonate of ammonia, digitalis, and gelseminum. The iodide and bromide were omitted. Beef-tea.

October 3d. Slept four or five hours last two nights. Dejections following enemata each day. Urine passed voluntarily for first time to-day, patient demanding urinal. Quiet, not anxious to get out of bed, but very emotional, talking and crying a great deal; wanders constantly in mind. Tongue, yesterday, moist, soft, slightly coated. Evening temperature (yesterday), however, rose to 101.3°. Temperature to-day, A. M., 98.8°; P. M., 102°. Pupils react equally to light. Borborygmus on pressure.

October 4th. Three large, soft dejections last night; one in bed. Temperature this morning, 101.8°, pulse 120. Urine high-colored; is passed involuntarily. Evening temperature, 100.8°.

October 9th. Is still very stupid and almost unconscious, although he protrudes tongue when asked. Has had diarrhœa for two or three days; defecation and micturition involuntary. Nourishment consists chiefly of milk; takes whiskey.

October 11th. Much more conscious of surroundings. Pulse and temperature more nearly normal. Tongue moist; very slight coat.

October 14th. Yesterday, was wildly delirious, constantly talking to imaginary persons, but not in a frightened way, as previously. Slept poorly last night. To-day, is more sensitive to external influences and talks easily, though wandering in mind.

October 21st. Appears much better to-day. Tongue still red, dry, and fissured in the centre, moist on the edges. Fans himself, and talks of the "mugginess" of the atmosphere.

November 7th. Is much better. Has been able to sit up for the last few days.

November 10th. Well enough to go out-of-doors.

November 12th. Discharged on request.

The patient was transferred to the City Hospital, service of Dr. C. F. Folsom, to whose kindness I am indebted for the following notes:

On entrance, was so delirious that no history could be obtained. Very restless, constantly getting out of bed. Does not recognize those about him but supposes them to be other persons.

Tremor of tongue and limbs. Right pupil slightly larger than left; reactions of both to light sluggish. Well-marked atrophy of both optic discs. Is unable to stand with eyes closed. Marked loss of power of hands. P. R. exaggerated. Speech thick, indistinct. Pulse 100, respiration 24.

Was discharged two days later on request, not relieved.

He is believed to have been sent later to Danvers for a time, but he ultimately recovered — at least, to a considerable extent — and within a year had resumed, in part, the practice of his profession.

In this case we have a man of thirty-two, with a distinct predisposition to mental disease, and addicted for a considerable period to the excessive use of alcohol. Having continued the abuse of the stimulant after, at least, two attacks of delirium tremens, he finally, four weeks before entering the Hospital, and probably much earlier, is perceived to act in a strange manner, to have temporary lapses of memory, and hallucinations of sight and hearing. On entrance, he is found to be much in the condition of a patient recovering from a severe attack of delirium tremens — weak, with decided tremor of face and hands, and mentally affected, unable to realize his surroundings. Very shortly, fever was detected, and, instead of improving, he grew rapidly worse. The general weakness increased, and was accompanied by very marked and constant subulturn tendinum, and by continual plucking at the bed-clothes. The tongue was cracked, dry, and parched, and the general condition suggested that of typhoid fever. Mentally, he likewise became worse, having constant, rapidly-changing hallucinations, many of them terrifying and horrible, but many also, and the proportion of these increased as the disease progressed, of a not unpleasant character. He constantly imagined that he saw friends and acquaintances, who spoke and chatted with him. He talked aloud much of the time, often starting up suddenly and answering some subjective question. This condition of things continued for a month, being varied by periods of semi-coma, when he could with difficulty be roused to answer questions. The fever ceased at one time, to recur later. At the end of a month his

strength had improved, and there were no acute symptoms remaining. From this time his mental condition improved until he left the Hospital, only to grow worse afterwards, and to necessitate a still longer treatment before final recovery. (See temperature chart).

In this case, there is little doubt that there existed in the beginning that condition of chronic alcoholic poisoning so carefully described by Lentz, under the title of chronic hallucinatory alcoholism. This, possibly due to the withdrawal of stimulants, passed soon into an acute febrile condition, recurrent, and lasting about a month, to be followed in its turn by the ordinary hallucinatory alcoholic insanity (Magan's third form of alcoholic insanity).

The second case I have to relate is that of a liquor-dealer, thirty-two years of age, a native and resident of Boston. He entered the Carney Hospital, June 5, 1886, in the service of Dr. Ferguson, to whose kindness I am indebted for permission to make use of the records.

Previous history. Obtained from friends: One of the patient's uncles was insane for a time, and at the Worcester Asylum for six months. No record of any other mental or nervous affection in the family obtained.

Patient had been healthy, except as follows: He has been a constant drinker for two or three years, and at times has drunk very heavily. Last autumn, he had several epileptic fits, and he has fallen down stairs several times. Two weeks before entrance, he stopped the use of alcohol entirely for five days, but then resumed. He was at this time placed under the care of a physician, as he had begun to have hallucinations of sight, and was rapidly growing worse. Finally, being inclined to be violent, he was brought to the Hospital.

Present condition: On entrance, he appeared rational, but very nervous. There was tremor of the hands, and the patient was very weak, unable to remain standing. When put to bed, he plucked constantly at the bed-clothes — a prominent symptom all through his illness. A few hours after arrival he became quite delirious, having hallucinations of sight, and talking aloud in a disconnected manner.

Was ordered capsicum and a mixture of bromide and chloral.

June 7th. Quite delirious; slept about half an hour last night.

June 12th. Has been in a constant state of delirium, with hallucinations. Much plucking at the bed-clothes. Sleep poor; none last night. Bowels free. Takes nourishment well (beef-tea, milk, egg-nogg).

June 17th. The daily record shows but little change. He seems to understand something at times. When asked where he was, he replied, "in bed"; and, on being requested to repeat the answer, spelt "in b-e-d."

June 20th. Asked where he was last night, and, on being told, seemed greatly troubled, but soon forgot.

June 23d. Condition unimproved.

July 1st. Service of Dr. Bullard. When I first saw this patient, a few days previous to the beginning of my term of service, he was lying in bed, muttering or talking to himself, with evident hallucinations of sight and hearing. He was very restless, plucking constantly at the bed-clothes. The physical examination revealed nothing abnormal anywhere. The temperature was about 100° most of the time (most unfortu-

nately the temperature-charts have been lost). Pulse rapid, feeble. Examination of the urine gave negative results.

The weakness, temperature, and general typhoidal condition of the patient made us suspicious of some complication, as typhoid fever or pneumonia, but repeated and careful examinations gave no evidence in favor of either. There were no symptoms referable to the chest, and no abnormal physical signs in the lungs. There was no tympanites or abdominal tenderness; no rose spots. The bowels were regular.

July 4th. Temperature 100°, pulse 120. Condition unchanged.

July 6th. Temperature 99°, pulse 108. First sound over the aorta loud and clicking; second sound not heard there. Other cardiac sounds normal; no souffle.

R Tr. Digitalis m vii, i. i. d.

July 7th. Intelligence somewhat better. On the 5th, he used the stool for the first time: he had previously passed everything in bed. He now seems to understand questions a little better.

About this time, the patient was seen in consultation by Dr. Jelly, in order to determine the question of appointing a trustee for his property. Decision negative.

July 8th. Temperature 99° yesterday, 98.8° to-day; pulse 120 each day.

July 12th. No change. Patella-reflex doubtful; no ankle clonus. Fibrillary tremor of tongue.

July 15th. Is always worse in the afternoons, and during the last two has been so restless that he had to be kept in bed by force. He thinks that everything is on fire, and that he is being robbed, poisoned, etc.

July 17th. Constant attempts to get out of bed. Cannot be left alone for a moment.

July 25th. Intelligence much improved. Much more quiet.

July 28th. Knows physicians; calls them by name, and seems to realize that he is recovering from a severe illness.

August 4th. Seems to have his senses in full. Can talk intelligently, and knows all about his business affairs.

August 9th. Has improved steadily, and was, to-day, discharged.

In both the preceding cases we have to deal with patients in whom, we may presume, a certain tendency to mental disease exists. One had already himself been in an asylum; the other had had a near relative in one. In both, the existing affection was undoubtedly induced by addition to the excessive use of alcohol. The more prominent and noteworthy symptoms in these cases may be resumed as follows: (1) The duration of the disease, followed in both cases by recovery, in connection with (2) the peculiar temperature, rising at times to 102° or more; (3) the great weakness of the patient, especially in the earlier stages; (4) the typhoidal appearance; (5) the constant subsultus tendinum, and the plucking at the bed-clothes; and (6), which is less uncommon, the long duration of the peculiar form of delirium, which, in the beginning, precisely resembled that of delirium tremens, but continued for weeks, with a gradual change to less terrifying hallucinations.

I will not enter here into the question of the differentiation of these cases from typhoid fever and other

diseases, but will merely say that in the cases related there did not exist any of the more diagnostic symptoms generally seen in typhoid fever, except the general typhoid-like condition of the patient, and that in both cases the course of the temperature was unlike that usual in typhoid.

The medico-legal importance of such cases as these seems to me considerable. In both the preceding Dr. Jelly kindly consented to see the patients with me, in order to confirm my diagnosis, and to decide whether the patients were actually insane, and likely to remain so for a considerable period of time or whether the condition was a more or less temporary one, and the patient had a fair chance of recovery. In the first case, the actual question to be decided was whether the patient should at once be committed to an asylum, or whether it were advisable to wait; in the second, whether the patient was likely to remain in his actual condition so long that it was right and advisable that his property should be put in trust. In both cases the decision was in the negative, and rightly so.

I cannot help feeling, for these reasons, that it is very important that this class of cases should be early recognized, not only by specialists, many of whom have, undoubtedly, opportunities for observing them more or less often, but also by the general practitioner, into whose hands they, in the beginning, almost always fall. All the cases of this character that I have seen, or have been able to find accounts of up to the present time, have either been fatal within a few days, or have ended in recovery. At any rate, if death does not occur within ten days, the prognosis is more favorable than one would be led to suppose by simple consideration of the duration and character of the symptoms.

In regard to the pathology of these cases, although data sufficient to justify a decided opinion are wanting, certain facts bearing on this subject may be mentioned. Without entering into detail in regard to the pathological changes of the nervous centres, and their envelopes in alcoholism, we may refer to a few general results. Fournier states that autopsies after *acute alcoholism* in man show most commonly the following lesions: "cerebral congestion, more or less intense; meninges injected, veins and vessels of the pia mater gorged with blood, cerebral substance dotted with points, roughened (*sablé*), and, on section, permitting the escape of fine drops of blood; sometimes, also effusion of serum into the meninges."

In chronic alcoholism we find two classes of lesions in these organs: the one, which may fairly be classed as acute, though the result of chronic changes, comprising, for example, hæmorrhages, and perhaps some effusions; the other class, the subacute and chronic. Audhoui, writing in 1868, says: "There is no need, I think, of insisting on the form that the nutritive trouble affects in the nervous centres, thickening of the meninges, the production of false membranes on the cranial dura mater, adherence of the pia mater to the cerebral cortex, hypergenesis of the neuroglia, fatty degeneration of the nerve-cells, of the capillaries, etc.; all this is perfectly well known." We will only mention the names of Mann, Thompson, Potain, Barrell, among the many who have written on this subject.

Vulpian, in his "Clinique Médicale de l'Hôpital de la Charité," speaks as follows: "The pathological lesions (of chronic alcoholism) are, to-day, well

known: they affect at the same time the meninges and the nervous centres. The lesions of the meninges are shown by thickenings, opacities, adhesions, etc.; those of the nervous centres by increase of the interstitial tissue, by destruction of the parenchyma, etc."

For a thorough and detailed description of the pathological anatomy of the nervous system in chronic alcoholism, we would, however, refer the reader to Lentz's book, "De l'Alcoolisme." In this the whole subject is carefully considered, and everything known at that time (1884) is stated. All pathological changes in chronic alcoholism may be referred to one of three distinct processes—circulatory troubles (congestion and inflammation), interstitial modifications (sclerosis), and fatty degenerations (steatosis).

In regard to the superacute form of delirium tremens we may mention two varieties, the "forme suraigue" of Delasiauve, and the delirium tremens febrile of Magnan. The adynamic form mentioned by Krafft-Ebing is probably only the secondary stage of the more violent forms. Krafft-Ebing refers Magnan's variety to delirium acutum.

Delasiauve's form is described by Lentz as follows: "The forme suraigue of Delasiauve is remarkable particularly for its violence, its agitation, the intensity of the delirium and the gravity of the general condition. The nervous activity is prodigious: the patient has neither respite nor repose, no part of his body is free from movement; his face bloated, red, even violet, is contorted through the quivering of the muscles; his eyes roll in their orbits; his skin is hot and burning, is moist with a profuse and sticky sweat, which sometimes emits an alcoholic odor. The tongue may preserve its natural moistness; more often it is dry along the edges, and its surface as well as the edges are covered with fuliginous crusts. Usually the thirst is excessive, unquenchable; the respiration more or less labored; the alteration of the features indicates a profound prostration. As to the pulse, sometimes rapid and feeble, at other times it contrasts by its almost normal rhythm with the other symptoms. The mind is assailed by hallucinations whose rapid succession causes an incessant change. The words crowd each other so in the patient's mouth, that several demand utterance simultaneously and escape with difficulty in jerky, interrupted, often unintelligible sentences. In constant agitation (jactitation), the head and hands are moved abruptly in all directions whence the imaginary impressions seem to arise."

Magnan's form differs but little. Its principal distinctive feature is the rise of temperature which is apt to run high and reach 40°C. (104°F.) or even 42°C. (107.6°F.). This lasts without remission for two or three days or perhaps longer, and if not followed, as is usual, by a fatal result, gradually descends to the normal limit. This form also, is marked by the constant presence of muscular movements, subultus tendinum, jerks and contractions of the muscles all over the body and by the extreme muscular weakness which eventually results from this incessant activity. Lentz considers that the only symptom by which this form can be differentiated from that of Delasiauve is the possibility of prolonged remissions in which the consciousness may for a time become quite clear.

The presence of a high and continued fever during an attack of delirium tremens, is always a symptom of most serious import. It denotes either the presence of some severe and dangerous complication, as pneu-

monia or meningitis, or it implies, as is thought to be the case at times, by certain authorities, an affection of the cerebral heat-centres, and thereby a wide-spread and dangerous condition of the cerebrum. In ordinary cases of delirium tremens, there is no rise of temperature whatsoever.

Näcke says: "In a series of examinations of a small number of cases (eleven), a slight feverishness could be determined in one-third of them. The maximum was 38.8°C., 101° F. Any temperature above this, pointed to some internal inflammation, more especially pneumonia. In our cases a slight fever appeared in the evening only, as a slight rise of the physiological evening exacerbation of the temperature, never in the prodromal stage, commonly only on the first, rarely on the second day of the true delirium. Pulse and respiration were commonly only slightly increased in rate."

The cause of the fever in febrile delirium tremens is still doubtful. Magnan gives the results of five autopsies in which little definite was found beyond the injection and edema of the cerebral meninges and a similar condition of the meninges of the spinal cord with injection of the gray substance of the latter. He himself, says that besides the hyperæmia, which sometimes ends in hæmorrhage and thus attests the very violent irritation of the nervous centres, we scarcely find at the autopsy anything except the more or less advanced alterations of chronic alcoholism.

That delirium tremens may be complicated by meningitis, is, of course, well-known, and many instances have been published, of which, however, I will only refer to the cases of Bonnemaison.

Whether such complication exists in any special case, can, of course, only be decided after a careful consideration of all the symptoms.

Whether in the febrile cases ending in recovery, the fever is due to complications meningitic or otherwise, or whether it is simply due to the violence of the cerebral irritation and the affection of the cerebral heat-centres has not yet been proved. The evidence in favor of the latter condition is up to the present time wholly negative. Considering the existence of heat-centres, as shown by Dr. Ott and others, proved, since no other cause of the high temperature is apparent, and since cerebral irritation evidently exists, it is assumed that the fever is due to the irritation of these centres. It must be remembered, however, that this is only a theory with some plausibility in its favor.

Näcke is in favor of this view. As in Magnan's cases the temperature cannot be simply dependent on increased muscular action "since now at the autopsy of such patients, beyond the more or less marked hyperæmia of the central nervous apparatus, and the changes produced in the system by chronic alcoholism, nothing was found which could explain the violent fever, we must in these cases regard the fever as directly dependent on the action of the lately introduced masses of alcohol upon the heat regulators."

We, however, do not believe that this question can yet be decided without further evidence.

Clinical Memorandum.

AN ANOMALOUS CASE OF HÆMATURIA.

BY FRANK DUDLEY BEANE, A.M., M.D., NEW YORK.

Miss —, aged twenty-eight years, U. S., brunette, bilio-nervo-sanguine temperament, teacher, came under my care February 8, 1886. Mother died of phthisis following pneumonia; father, sister, and brother living, in good health. No hereditary tendencies. Six years ago the patient had pneumonia, with rapid and complete recovery. About three years ago, she suffered from chills and fever for a time, but has had no return, even in a modified form, for over two and a half years; namely, since she changed her place of abode. Habits of life good. Around the New Year of 1886, Miss — contracted a severe cold, treated it with simple remedies, and expected her distress to quickly disappear. But head- and backache and general *malaise* persisted; she also noticed that her urine was very reddish, and left considerable deposit in the vessel. This state of affairs continuing for about a month, she consulted me. Her headache was mild, of the character of a "fulness." The backache, across the loins, also mild, but, like the headache, constant; a slight general *malaise* present, but not incapacitating her for attending to her daily duties; no nausea at any time. Digestive organs, heart and lungs, organically and functionally normal; menses regular and normal; no vaginal or uterine disease; urination normal as to amount, frequency, absence of distress. Injury, emotional or medicinal cause, hæmophilia, purpura, and malingering were out of the question. Careful examination of the urine resulted: acid, 1030, free from sugar, pus, renal epithelium, casts, etc., but large numbers of blood-corpuscles present, and account for the albumen found.

Diagnosis: *Hæmaturia ab causâ ignotâ.*

On the theory of a possible passive renal congestion from vaso-motor disturbance, I ordered infusion of digitalis and sweet spirits of nitre. Two weeks' regular and continuous use only resulted in somewhat modifying the head- and backache. In view of the possibility of a malarial cause, she was treated for two weeks with quinia (0.35), tannate of iron (0.10), t. i. d., with no effect upon the bloody urine. Nine days under tannate of iron and caffeia, with sweet spirits of nitre and fluid extract of triticum repens, gave no result, except an increase in the amount and

lighter color of the urine. Quinia (0.20), hydrastia alba (0.10), and auro-sodic chloride (0.005), thrice daily for ten days produced no diminution in the hæmaturia. For the following eighteen days the patient took three pills of ergotin (5a gr. iii, Schieffelin) two hours after meals (that is, thrice daily), with no permanent improvement. For a day, now and then, a slight change for the better would be noticeable, then the amount of blood in the urine would be as great as ever. The headache, however, had disappeared; a slight backache remained. Mild physiological effects of the drug, such as slight dizziness and drowsiness, were present most of the time. On this account, I considered it prudent to make a change; therefore, for two weeks thereafter, she took a pill of ferri tannas, acid. gallie. et fol. digitalis, with the same effect as that produced by the ergotin. For the next ten days the ergotin treatment was resumed, with little or no benefit. From May 11th until June 12th, she faithfully took 0.10 of a 1% solut. glonoin thrice daily, but the picture became no brighter. On May 25th, I detected for the first time what appeared to be epithelia from the kidney pelvis (?); only two scales out of four specimens examined.

June 22d. She has been taking one gramme tr. iodine co. thrice daily for ten days. After five days' use, the urine "was lighter and showed less deposit, but the very next day there was a heavy deposit of what looked like congealed blood, and two days ago the same thing occurred" (patient's report). To-day, for the first time, I detected *one large hyaline cast* in six slides examined. Despite this continuous loss of blood, the patient has gained three pounds of flesh!

Concluding that this might be a unique, undescribed form of incipient chronic nephritis, a consultation with a prominent genito-urinary specialist followed. The opinion of incipient nephritis was endorsed, my view of a sojourn at a mountainous region, with strict attention to the skin and diet, approved, and a resumption of the ergotin recommended. On July 1st, I advised a Turkish bath every fifth day, in addition to the daily sponging and brisk rubbing with a flesh-brush. On July 9th, I urged her to journey to and remain in the Adirondack region for, at least, two months. There had been no improvement whatever in the hæmaturia, the only remaining sign of physical derangement. In September following, on my return from my vacation, I notified Miss —, but she did not report. In the early part of February last, I learned the following from a perfectly reliable source:

Instead of following the plan advised in July, the patient shortly afterwards began taking a nostrum said to be composed of hepatica and potassic nitrate as active ingredients, some claim the presence of a small amount of digitalis, and, in the meantime, continuing (as before) the daily examination of the urine (deposit method). By the time one-half the contents of the first bottle had been consumed, the urine became lighter in color, and the deposit less copious. Progressive disappearance of the blood followed, and had wholly (as far as objective examination could decide) when two bottles of the remedy had been taken. No further treatment was followed, and not the slightest relapse occurred. Skeptical as to the completeness of the cure (*sic*), I was enabled to make five most searching chemical and microscopical examinations of urine, passed before breakfast, and promptly delivered to me on February 15th, 17th, 22d, 23d, and

24th. Each specimen was normal in every respect. The lady has remained perfectly well and free from all urinary abnormalities to the present time (November 1st).

The consultation of a large number of authorities brought to light no similar case, and afforded me no further satisfaction than the following words of Roberts,¹ the italics being mine: "Cases also occur which are not referable to any of these categories, of which the origin is extremely obscure." Shall we accept the *post hoc* result as a legitimate *propter hoc* effect of the nostrum, or rather, attribute the coincident disappearance of the disease to the *vis medicatrix nature*, which, up to that time, had refused, or been unable to act because of the operation of certain unknown intimate systemic hindrances?

Reports of Societies.

BOSTON MEDICO-PSYCHOLOGICAL SOCIETY.

E. B. LANE, M. D., SECRETARY, *pro tem.*

MAY 19, 1887, DR. GEORGE F. JELLY in the chair.
DR. W. N. BULLARD read a paper entitled

CASES OF FEBRILE DELIRIUM TREMENS.¹

DR. BOLAND saw a similar case of meningeal trouble in a drinking man. Hebetude was the most marked mental symptom. The temperature was similar to that in Dr. Bullard's cases. It was called a case of typhoid. The man died, and, at the autopsy, one and a half to two ounces of pus were found beneath the dura, and none of the lesions peculiar to typhoid were found. The highest temperature was 103°.

DR. FOLSON had treated the first case reported by Dr. Bullard at the City Hospital. The case resembled one of general paralysis from the ataxia, although the mental condition was quite different. For certain economic reasons, he was removed to the Danvers Lunatic Hospital. The ataxia in this case was due to the usual lesion in such cases; that is, peripheral neuritis. This is shown by sensitiveness to pressure over the nerve-trunks and atrophy. This case had been in an asylum at the age of fifteen. He was then active; had numerous hallucinations of sight and hearing, with delusions.

He spoke of another case who was never seen drunk, but inquiry among the servants revealed the fact that he was in the habit of getting drunk every night. As in the former case, there were delirium and peripheral neuritis, shown by emaciation of the legs and tenderness. This was thought by one surgeon to be a case of general paralysis. The mental state of these cases is that of dementia. They are extremely filthy in their habits and language. They look discouraging, but they usually recover.

DR. BULLARD called attention to a similar class of cases, described by Magnan as *febrile delirium tremens*.

DR. FOLSON questioned whether Magnan did not describe a different class of cases.

DR. CHANNING questioned the propriety of the name selected by the reader for the group of symptoms described. The temperature in these cases was not unlike that seen in cases of mild, acute mania.

¹ See page 144 of this number of the Journal.

¹ "Urinary and Renal Diseases," Philadelphia, 1885, p. 159.

DR. BULLARD said that neither of his cases was maniacal. The condition was rather a typhoidal one. He was not sure that there was a meningitis in these cases. While it is true that in some of Magnan's cases of febrile delirium tremens the temperature rose, as a rule, it fell off.

DR. COWLES saw several similar cases at the Boston City Hospital. Often, the delirium continued for some time. Examination was usually made with reference to a commitment to an asylum, but usually the commitment was postponed. These cases are of interest from their resemblance to general paralysis.

He had seen a case of meningeal trouble in a drinking man who was sent to the McLean Asylum. There were hallucinations of sight and hearing, and fumbling of the bed-clothes. The patient's condition was very low. He was apparently about to die, yet he made a good recovery in a few months. This case would drink much without showing it.

In another case, a man drank heavily for years. There were several symptoms of general paralysis manifested, and an unfavorable prognosis was given. The condition of this case was not as low as in the one just described, but delusions persisted for a long time. He, too, made a good recovery.

DR. JELLY said he saw Dr. Bullard's cases, and spoke of the difficulty of deciding between typhoid fever and delirium tremens on first seeing them. The first case he had thought would die. This case he considered subacute meningitis. The second case, he thought, would clear up.

He then spoke of the cases Dr. Cowles had mentioned. The first case was very different from those described by the reader. The condition was not as low, the patient was more active and extravagant, and wrote for the papers. The other case he had examined repeatedly, but had refused to commit him to an asylum. As the patient grew stronger physically, he became more violent, but it now transpires that he was allowed liquor. While he thinks it may not be right to call this condition acute meningitis, he is willing to call it subacute meningitis.

DR. BULLARD said Magnan classes acute and chronic cases together, under the term of febrile delirium tremens; they begin alike. In all cases where the temperature remains up death follows, and an autopsy reveals cerebral and spinal meningitis. He did not wish to insist on the diagnosis he had offered, but, for lack of a better term, he had temporarily decided on the title of his paper.

MASSACHUSETTS MEDICAL SOCIETY.

COUNCILLORS' MEETING, WEDNESDAY, FEBRUARY 1.

A STATED meeting of the Councillors was held at the Medical Library, Boston, on Wednesday, 1st inst.

The meeting was called to order at 11 A. M. by the President, DR. THOMAS H. GAGE. Seventy-seven Councillors indicated their presence by signing the roll.

On nomination by the Chair, the following delegates to other State Medical Societies were appointed:

Maine: Drs. A. H. Johnson, of Salem; J. O. Marble, of Worcester.

New Hampshire: Drs. F. W. Draper, of Boston; B. H. Hartwell, of Ayer.

Rhode Island: Drs. R. L. Hodgdon, of Arlington; G. C. Webber, of Millbury.

Connecticut: Drs. A. M. Smith, of Williamstown; G. D. Colony, of Fitchburg.

New Jersey: Drs. A. Hosmer, of Watertown; A. C. Deane, of Greenfield.

Committees were appointed:

To Audit the Treasurer's Accounts: Drs. A. Wood, S. J. Mixer.

To Examine the By Laws of District Societies: Drs. S. D. Presbrey, J. C. White, F. W. Chapin.

The Committee on Membership and Finances reported names of Fellows to be allowed to resign, to retire, to have dues remitted, and also to be dropped for non-payment of dues, and their recommendations were adopted.

The Committee on Medical Diplomas, to which, at the meeting in October last, was referred the question of Fellowship in the Society, as embraced in By-Laws I. and II., reported, and recommended the repeal of the following sections of the concurrent vote of the Councillors and Society, October 7, 1874 (By-Laws, etc., pp. 27, 28):

That tickets or diplomas of Botanic, Eclectic, or Homœopathic colleges, or of colleges devoted to any peculiar or exclusive system of medicine, are considered irregular, and will not be recognized under any circumstances;

And that certificates from teachers who practise any peculiar or exclusive system of medicine, who advertise, or who violate in any way the code of ethics adopted by the profession in this State, will not be taken, even though the teacher himself be a regular graduate in medicine.

The Committee stated that by the adoption of this recommendation by the Council and Society it would be possible for the Council to add to the list of schools, whose diplomas are recognized for the purpose of admission to the Society, such eclectic and homœopathic schools as furnish the education required by By-Law I.; and the graduates of such schools who have renounced eclecticism, homœopathy, or other exclusive dogma, would become eligible to examination for admission to the Society.

The report of the Committee was accepted, and its recommendations were adopted.

The Committee appointed at the last meeting to consider the question of arranging meetings of Sections of the Society in some of the departments of medicine at the time of the annual meeting, presented the following recommendations, which were adopted:

That, beginning with the annual meeting in 1889, the hours of the afternoon session of the first day be occupied by meetings in Sections of Medicine, Surgery, and Obstetrics.

That the Committee to Procure Scientific Papers arrange for the organization of the above-named Sections, and, in preparation of the meeting, select topics of interest, and such as are capable of general discussion in their appropriate Section.

That the President be requested, in nominating the Committee to Procure Scientific Papers, to select its members with reference to the formation of these Sections.

That the Committee on Publications be requested to consider the advisability of providing for accurate reports of the discussions which follow the reading of the papers presented in the Sections.

NEW YORK NEUROLOGICAL SOCIETY.

MEETING held December 3, 1887. The PRESIDENT, DR. C. L. DANA in the chair.

DR. J. C. SHAW reported

A CASE OF CEREBRAL TUMOR.

The patient was a male, forty-one years of age, a jeweller by trade, temperate and previous history good. No syphilis.

In 1879 the patient had an attack of rigidity in the night followed by a deep sleep. March 19, 1882, he had an epileptic attack, the convulsion commencing in the left side of the face and extending to the neck so that the head was twisted to the left side, the eyes were turned upward. Thus far the patient was conscious, and had raised the left arm to strike upon his bench to attract help when his arm was seized with the spasm, and he knew nothing further. The attack was followed by sleep. He had had as many as four such seizures in a week. In one attack observed by the speaker, the left side of the face and the left arm had been principally affected. There had been no loss of consciousness in this attack.

The convulsions were preceded by a peculiar painful sensation in the roof of the mouth and teeth. There was more or less numbness of the left side, the tactile sensibility of which was diminished. Two points were recognized upon the left hand only when 4 cc. distant, while upon the right hand two points were recognized when 1 cc. distant.

January, 1886, headache commenced to be complained of, also nausea. Choked disk was now found. August, 1886, vision was almost lost. Headache and nausea continued, and mental cloudiness was apparent. February 4, 1887, the patient would fall to the right side, there was paresis of the left arm and leg and the patient could not tell when lightly touched. He was now weak, thin and confined to the bed. March, 1887, urine and feces were passed involuntarily. In May, a bed sore appeared. June 21st, the patient suddenly became comatose with puffing respiration chiefly abdominal. After thirty-six hours he recovered from this, but July 1st, died of exhaustion, extremely emaciated. The skull was found very thin, the veins of the meninges prominent. On lifting the brain, the posterior fossa was found to contain fluid, the origin of which did not appear. The left hemisphere showed no gross lesion. In the right hemisphere, the dura was adherent throughout a localized patch, dark-brown in color and occupying the lower part of the motor zone, beneath which softening appeared. The basal ganglia were free.

The pain in the teeth complained of at the commencement of the spasms had suggested a reflex from the dura to the fifth nerve. The reader considered it not illogical to conclude that the numbness, too, was to be explained by the irradiation of this reflex to other portions of the sensory tract. The apoplectic form seizure was probably due to hæmorrhage into the softened mass. The opinion of the members was requested upon this point.

DR. DANA inquired in regard to the character of the growth.

DR. SHAW replied that section had not yet been made, but he considered the growth a glioma.

DR. DANA found the growth occupying only the lower part of the ascending frontal, and not involving the parietal lobe.

DR. SEGUIN remarked that as the pia was *in situ* exact location was difficult; but that according to his judgment the lower part of the præcentral and the posterior extremity of the second frontal and of the third frontal convolutions were involved. The fact that Dr. Shaw had observed no laryngeal symptoms was interesting.

DR. BIRDSALL, referring to the sensory symptoms, remarked that the tumor was not simply a cortical lesion, it extended inward, and more central tracts had probably been involved.

DR. STARR added that sensory symptoms accompanied motor impairment, where the parietal lobe was invaded. As a rule, where cortical motor lesions were without sensory disturbance, the location of such lesions was anterior to the fissure of Rolando. Where sensory disturbances were also found, it was posterior to that fissure. In this case, however, it was not impossible that congestion posterior to the fissure would explain the symptoms.

DR. SEGUIN remarked that the subject of sensory disturbance in connection with cerebral tumors was most interesting and important. In his own experience a slight diminution of sensibility had accompanied lesions of the motor centers even when confined to the cortex. Nothnagel, at the Congress for Internal Medicine in Germany, had referred to slight tactile anesthesia in a large number of cases of tumor or lesion of the motor cortical centres. These were, however, without loss of the muscular sense. It was conceded that the muscular sense was located in the parietal lobe. In a case of Dr. Weir's with sarcoma involving the fasciculus for the face and hand, there was distinct anesthesia of the face and hand, but no loss of the muscle sense as tested by passive motion and weights.

DR. PUTNAM recalled a case of tumor which sprang from the falx between the two hemispheres and perforated the skull. At the time of death the whole left side was contracted. In this case numbness of the left wrist had preceded the motor symptoms. This tumor was posterior to the fissure of Rolando.

DR. FISHER asked the opinion of the meeting in regard to hyperæsthesia and pain under these circumstances. He recalled a case in which with the symptoms of a tumor restricted to one side there was great increase of sensitiveness and pain.

DR. STARR presented a case of combined sclerosis in connection with Dr. Putnam's paper. The patient had been under his care at the Polyclinic for nine or ten months. He was sixty-two years of age, of good family history and no syphilis. Eight or nine years ago he had commenced to complain of dull aching pain in the sacrum and down the legs. He had had no lightning pains but a progressive difficulty in locomotion until he was now markedly ataxic. There was increased tendon reflex at the knees. The case differed from that of ordinary locomotor ataxia in the absence of lightning pains, and the absence of the loss of the tendon reflex. There had been slight enuresis, but the urine was now retained. The pupils were contracted, but were not of the Argyll-Robinson type. They reacted both to light and to accommodation, but sluggishly. The tremor of the muscles of the face referred to by Gowers was present. It was a light tremor like that of parietic dementia.

The Chairman then introduced Dr. Putnam, of

Boston, the President of the American Neurological Association.

DR. PUTNAM presented a

REPORT OF THE EXAMINATION OF THE SPINAL CORD
IN A CASE OF COMBINED SCLEROSIS.

The patient was a female, fifty-eight years of age, whose father had died at eighty, and mother at eighty-three years. The patient had been divorced from a first husband on account of immoral conduct. Her second husband was also dissolute. When twenty-eight or twenty-nine years the patient's hair had fallen out. There had been no eruption noticed. The patient had used stimulants freely, but never in excess. Beginning in 1880 she had suffered with diarrhoea. Brown discoloration of the skin of the left arm and neck was then noticed. Subsequently the skin of the abdomen became a deep chocolate color and the pigment of the nipples and axillæ increased and deepened. When first seen by the reader her face was as dark as that of an Indian, and roughened with scales and exudation. In 1883 she was treated for anæmia and dyspepsia, the nerve affection not having appeared until two or three years ago. The first nerve symptom was numbness in the fingers. In November, 1886, she had lost power in the limbs, so that her gait was unsteady. She had difficulty, also, in the use of her hands, and was said to have fainted at one time with her teeth clenched. Her motor inability consisted in incoordination rather than paralysis. She had no lightning pains, but closing the eyes increased the incoordination, failing to reach the spot aimed at with her hands within four inches. On account of her mental apathy her sensory condition could not be made out. Her answers to questions were not correct. She had a ravenous appetite and the diarrhoea continued. Taste had been impaired for several years. During the following six months the legs became completely paralyzed, and the patient died April 8, 1887, six months from the onset of the ataxia and the paraplegia. The symptoms of ataxic dementia were prominent in the ravenous appetite and disordered taste, leaving the diagnosis perhaps open to question as examination of the brain was not permitted. Spitzka has found degeneration of the lateral tracts in dementia, but coincident degeneration of the pyramidal tracts was not present in these cases.

The post-mortem examination showed in the lower ileum several ulcers, apparently tubercular in origin. In the cord there was softening of all the tissues at the level of the fourth dorsal nerve. There was extreme whiteness and no trace of vascularity in this part. The cord was examined from the region of the first lumbar to that of the second cervical vertebra. The posterior columns, through their whole extent, showed a condition like that of a primary sclerosis. At the level of the twelfth dorsal vertebra there were two sclerotic areas, one external to the column of Goll in the column of Burdach. The lateral columns appeared as described by Spitzka in his two cases of primary dementia. The septa between the nerve-spaces were broken down so that holes appeared in the sections with fragments of myeline and granular cells. These changes were confined to the lateral pyramidal columns, up to the middle cervical region where the direct cerebellar tract of both sides took on the same appearance and the diseased lateral area became less.

It was noted that the softened spot might have been due to anæmia or to myelitis. It was against the latter theory that the vessels were here shrunken and there was no transudation of white globules to be seen. The degenerations were not in direct relation with this softened tract. The posterior nerve-roots were healthy. The anterior nerve-roots were affected with different degrees of inflammation.

The reader referred to Strümpell's and Gower's classifications, also the general question of primary systematic sclerosis of the spinal cord.

DR. STARR considered that the exhibition of specimens placed the diagnosis of combined sclerosis in this case beyond doubt, and inasmuch as the case had presented symptoms not recognized as belonging to this condition, the paper was one of unusual service, by enlarging our clinical picture of the disease. The exact pathological difference between the condition of vacuolization in the lateral column and that of the ordinary sclerosis of degeneration was a matter of interest. In these specimens the lateral columns were vacuolized and in the posterior columns the connective tissue was increased; yet both processes were called sclerotic, when they probably should be differently classed.

Dr. Starr presented sections, one from the original case of Friedreich's disease, and one from a case of ordinary sclerosis, each presenting the distinctions referred to in Dr. Putnam's paper.

DR. SEGUN considered the change in the lateral columns in Dr. Putnam's specimens in front of the region of the crossed fasciculi. In one section it was even in front of the transverse diameter. The same violation of the limits of the pyramidal fasciculi had been observed in a case of his own. In this case the paresis predominated and the patellar and solar reflexes were exaggerated. In another case referred to him by Dr. Hun, of Albany, ataxia and posterior column symptoms predominated, and there was no tendon reflex. There was anesthesia, fulgurating pains, and ataxia of the legs and hands with gradual paralysis. One or the other lesion would predominate in such cases, producing variety in the symptoms. Errors in diagnosis were easy. Nodular or insular sclerosis, if distributed in the posterior and lateral columns, would give the clinical picture of combined sclerosis. Charcot had even lectured upon a case as spastic paralysis, to find upon autopsy nodular or insular sclerosis. Diagnosis should be guarded.

DR. BIRDALL, referring to the specimens under the microscope, found in the posterior columns ordinary sclerosis, and in the lateral columns separation and swollen myeline sheaths, the axis cylinders being in position in some places, and in others simply spaces between the neuroglia elements as though the myeline and axis cylinders had dropped out. In judging of this condition, one had to remember the differing normal structure of the two regions, the finer fibres and finer neuroglia elements in the posterior columns. With Dr. Seguin, he found the degenerated area forward of the transverse line of the central canal and extending even half-way up the anterior horn, taking in the region described by Gowers as the ascending cerebral tract, obtained by physiological and embryological data. The speaker inquired whether there had been any chance for post-mortem softening of the cord which would explain the vacuolization.

DR. PUTNAM thought that there had not been any

such chance as the specimen had been dropped into Müller's fluid within one hour after removal. The nature of the change in the latter column showed that it had been rapid from the fragments of granular myeline scattered about, and it was suggested that the spaces might have been produced by albuminous fluid which had been poured out and coagulated. The section showing the degenerated area anterior to the transverse diameter, had been taken from the upper cervical region, where the direct cerebellar tract carries the area forward.

Of the three varieties of mixed sclerosis, the spasmotic was represented by a case of Strümpell's, the ataxic by Dr. Starr's case, and the paralytic by a case of Strümpell's and his own.

DR. DANA had given special study to this class of cases, and saw no reason to change the opinions formed one year ago. The classification referred to as Dr. Strümpell's, had been arrived at by himself before reading Dr. Strümpell's paper. It would probably occur to any one who studied the subject. The most frequent combination was tabes with paralysis atrophy and contractures. In other cases the tendon reflex and ankle clonus disappeared last and the patient becomes a case of typical tabes before death. Dr. Putnam's case resembled his own, and he believed the trouble to have been primarily a myelitis encroaching upon the gray matter and extending up and down. The vacuolization was an argument in favor of secondary change, he had seen it in several cases following an acute myelitis.

DR. PUTNAM stated that as the degeneration was found both above and below the softened area, it could not have been secondary to it; also the involvement of the whole lateral tract would have required a focal lesion above, which was not obtained.

DR. DANA presented the calvarium and brain of a young woman trephined over the site of an old fracture for epilepsy and maniacal attacks. The operation had been done by Dr. Robert Abbé with all antiseptic precautions, yet persistent high temperature followed, with death on the tenth day.

A small subdural cyst was evacuated at the time of the operation. The autopsy showed old leptomeningitis with recent meningitis and acute red softening under the injured part. The question of the safety of trephining was brought up.

Recent Literature.

The Medical Register for New England. By FRANCIS H. BROWN, M.D. Boston: Cupples & Hurd. 1888.

A mere list of the principal contents of this new edition of Dr. Francis H. Brown's "Medical Register for New England" is sufficient to show its absolute indispensability for medical practitioners, dentists, and pharmacists in active business all through the New England States for almost daily use, and its utility as a book of reference for many outside of New England—provided the work is carefully done, and of this Dr. Brown's painstaking accuracy, as exhibited in previous editions, is a sufficient proof. This new edition contains forty more pages than the last edition of 1884, and is more clearly printed. Among its valuable contents is to be found statistical and practi-

cal information concerning medical, dental, and pharmaceutical societies and associations, hospitals and dispensaries; charitable asylums; professional institutions of education; laws and ordinances relating to medical men; lists of medical examiners (coroners); pension surgeons; medical officers of the State militia and public institutions; museums, libraries, prizes; lists of surgical instrument makers, chemists, microscope dealers, etc., together with descriptive and local lists of members of the New England medical societies.

The lists of members of State medical societies were received from and revised by the secretaries of the societies, and are as correct as such lists can reasonably be made. A liberal amount of space is also devoted to a short history, to the form of organization, and to a list of the officers and New England members of all the important national medical societies and associations.

The Practice of Medicine and Surgery Applied to the Diseases and Accidents Incident to Women. By W. H. BYFORD, A.M., M.D., and HENRY T. BYFORD, M.D. Fourth edition. Philadelphia: P. Blakiston, Son & Co. 1888.

Dr. Byford's work, the fourth edition of which has just appeared, comes with much fresh matter, and a very thorough revision of the old. It is a personal book, embodying largely the results of the authors' extensive experience, and borrowing from others only to a limited extent. He labors under the disadvantage of not possessing a good style, so that much of what he says fails of its due effect from lack of clearness of description. This is especially true of the first few chapters on the "Anatomy and Physiology of the Female Pelvic Organs," and the "Examination of the Female Pelvic Organs." There is so much minuteness of detail that it strikes the reader as unnecessary and tiresome, especially as the descriptions are difficult to understand.

This criticism applies with most force to the theoretical part, for when the author comes to the discussion of the various forms of uterine and pelvic disease, he is interesting and instructive. The book cannot, perhaps, vie with other well-known text-books, nor does it seem to us well adapted to the needs of the student, but the general practitioner and the specialist will find it well worth their while to own and consult it. There is a great deal with regard to the general treatment of uterine disease and its complications, which is very rich in suggestions.

The illustrations, many of which are original, add distinctly to the value of the work.

—Dr. J. D. Whitehouse, of Santiago de Cuba, reports to the *Medical Record* a case of poisoning (non-fatal, but with severe symptoms), in a young girl, from seven-and-one-half grains of antipyrine.

—English patients and physicians at Maloja and Moritz are signing quite extensively a memorial to the Swiss Government to permit English physicians to practice there, which was prohibited by statute recently. The petitioners say that they went to these places expecting to be treated by their compatriots and that if the restriction remains in force, they will be forced to go away, and the popularity of these resorts among English-speaking people will be seriously affected.

THE BOSTON
Medical and Surgical Journal.

THURSDAY, FEBRUARY 9, 1888.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States and Canada; \$6.00 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 94 Boylston Street.

All letters containing business communications, or referring to the publication, subscription or advertising department of this journal, should be addressed to the "Manager of the Business Department," Medical and Surgical Journal, 94 Boylston Street.

Remittances should be made by money-order, draft, or registered letter, payable to

THE COMMITTEE OF THE PHILADELPHIA
 COLLEGE OF PHYSICIANS AND THE NA-
 TIONAL QUARANTINE.

We have already reviewed, with editorial comments at some length,¹ the report of a Committee of the College of Physicians of Philadelphia appointed "to consider the present danger of the importation of cholera into this country, and to secure concerted action among the medical societies in urging upon the State and national authorities the adoption of a uniform and efficient system of quarantine for all exposed ports." This report was made to the Society October 28, 1887, and is now reprinted, together with an address from the same Committee (Drs. J. C. Wilson, Shakespeare, and Cleemann) to the medical societies of the United States, repeating their recommendation that the societies take strong and immediate measures to secure Government management and control of quarantine.

It is not pertinent to the question to discuss the general matter of quarantine, although a great deal might be said of the value of a cholera-scare in inducing local authorities to make sanitary improvements, and to adopt a health-code of lasting value. There might even be a suggestion that more permanent good would come to the city of Philadelphia by sustained efforts to improve the character of their rulers, and to clean out some of their filth than by any quarantine agitation. There are, too, Philadelphians who think that an epidemic of cholera in their city would be an actual benefit to them from that point of view.

However, we are quite willing to admit the need of a sensible medical inspection at our ports of entry adapted to the individual requirements of the several ports; but we insist that it should be practical, and not, for instance, make the same requirements in two cities having such different climates, local conditions of filth, character of commerce, and distance from pestilence-centres, as New Orleans and Boston. We have already referred to the very inefficient quarantine at New York, as shown by the report of the New York State Board of Health and by the discussion at

the last meeting of the American Public Health Association. We are quite prepared to admit the Philadelphia Committee's statement that Baltimore and Philadelphia are worse.

The query naturally arises, first, whether Government control of quarantine is practicable in case it is considered wise. We believe not. We should oppose it in Boston, because we think that our medical inspection is better than any the National Government would give us, and because we would prefer to take our chances of correcting any defects or mal-administration through local, rather than through general, officers. New Orleans would take the same ground, and other important ports, for one reason or another, would do likewise.

In the second place, is the measure wise? We also believe not, at least not at the present time; and one of the strongest arguments for our belief is the report itself of the Philadelphia committee, which strikes us as being theoretical, and not based upon sufficient investigation and knowledge. We feel quite sure, whether we should be ultimately prepared to advise a general government quarantine or not, that any measures adopted now to secure that end, even if successful, would result only in disappointment. We doubt whether it will ever be practicable to so harmonize and adjust the conflicting interests of the several States as to make a national system of maritime quarantine practicable. At all events, it might be well to see how we succeed in wrestling with the tariff question; and then go to Congress, if we think best, with our national medical inspection at ports, but only when we have ready a definite plan worked out to the least detail, and upon which the several health authorities can agree.

As to immediate measures, the greatest good has come from the Massachusetts law giving the State Board of Health coordinate power with the local Boards so that, if any town is not doing its full sanitary duty, the State can assume control, and do whatever the requirements of the case demand to protect the public health. Let this law be extended to every State in the Union, and, at the same time, let an Act of Congress be passed giving the government at Washington power to assume control whenever State and town are both derelict. If Dr. Davis's bill can also be passed for a Health Commissioner or Health Bureau connected with the Interior Department, we not only have good ground to stand upon, but we can gradually evolve a sanitary inspection at our ports and prominent railroad centres that will be efficient, practicable and satisfactory.

—The *London Medical Record* has undergone a change in its publishers and its name. It is hereafter to be called the *London Medical Recorder*, and the first number will appear on the 20th instant. The new series will be exactly the same in size and style as the old, with a reduction in price from 18s. to 12s. per annum.

¹ November 2, 1887.

THE SANITARY CONDITION OF THE WATERTOWN ARSENAL.

It appears, from what we learn, that heretofore in our army service, on account of the limited number of commissioned medical officers available to fill all the demands and requirements at so many different rendezvous, hospitals, depots, forts, etc., scattered over such a wide extent of country, the United States Arsenals have been compelled to depend upon neighboring physicians and surgeons, under contract, for attendance on the officers, enlisted men and their families.

Of late, however, since the Indian question is nearly, if not quite, settled, and the troops are being concentrated in large posts in regiments, the Government has considered it wise to make a change, and last summer ordered commissioned medical officers to duty at the arsenals in Watertown, Mass., Watervliet, N. Y. and Frankford, Pa.

It is especially gratifying to the medical profession that already, as will be seen by reference to the correspondence and report of Surgeon J. C. McKee, contained in Ex. Doc., No. 40, of the National House of Representatives in the first session of the Fiftieth Congress, an important improvement, which has been wanted, recommended and asked for many years back, will probably be carried out this coming spring and summer, near our homes in Boston.

Why this dangerous condition of affairs at the arsenal at Watertown, Mass., has been allowed to exist for so many years without attracting any attention, is one of those mysteries to which the proper explanation fails to present itself to the mind of the simple sanitarian.

In justice to Lieutenant-Colonel F. H. Parker, ordnance department, commanding officer, we are authorized to say that since he came in command, some four years ago, he has made every effort, by repeated reports, to have this improvement made. He also had plans and estimates made for the work, but Congress as steadily refused the appropriation until now the prospects look encouraging that the money will be forthcoming this session.

The request for an appropriation of \$11,908.96 for improving the sanitary condition of the Watertown Arsenal is now before the Appropriation Committee of the House, at Washington, with the endorsement of the Treasury Department, the War Department, and the Ordnance officer, and, as we have already said, by no means for the first time. Here seems to be a truly legitimate opportunity to dispose of a bit of surplus.

Between the middle of August, when he first reported for duty, and the middle of November, Surgeon McKee had two cases among those under his charge, of filth diseases, both assuming a malignant type and going on to a fatal termination in spite of treatment.

A calculation based upon the history of the Arsenal taken from its records, shows that the soil of the few acres of Arsenal grounds has been called upon

since 1814, to receive, absorb, and assimilate about one hundred and seventy-four tons of solid or fecal matter, and 11,098 hogsheads of liquid or urinary matter, in addition to a similar amount of slops, grease, etc., owing to the vicious and dangerous open cess-pool system which prevails. Under such circumstances we are not surprised that the report of the post-surgeon speaks of the soil, land and gravel as filled and saturated with putrid organic matters and ill-smelling gases, and of the conditions and surroundings obtaining at the Arsenal as in the highest degree favorable for the outbreak of epidemic disease.

Accepting the facts as stated, we most heartily endorse the further opinion expressed that, after this warning, further hesitancy and delay on the part of those in authority will not only be reprehensible but absolutely criminal.

THE MUSICAL PRODIGY, JOSEF HOFMANN.

NUMEROUS complaints having reached the Society for the Prevention of Cruelty to Children that the musical prodigy, Josef Hofmann, was injuring his health by his numerous public concerts in New York and other cities, a medical examination of the boy's condition was made at the office of Mayor Hewitt, last week, by Dr. Sayre, the physician of his manager, Mr. Abbey, Dr. Joseph D. Bryant, of the Health Department, and Drs. Janeway and A. McLane Hamilton. The conclusion at which they arrived was that his functions were at present all in good order, but, while there were no indications that his system had sustained any injury thus far from his public performances, they advised that in the future the concerts at which he appeared should be limited to four a week, and that, so far as possible, there should be an interval of one day between the performances. To this proposition the manager and Hofmann's father readily assented. Mr. Gerry, President of the Society named, has communicated to the father the offer of a citizen of New York to furnish a fund of \$50,000 for the education of the lad, provided he is not allowed to give public performances until he has completed a thorough course of study, and attained a substantial maturity of growth. Mr. Hofmann is said to have refused this offer, stating that, at least, \$100,000 would be necessary to provide a sufficient income for the purpose named: and it is possible that this amount may be raised by the admirers of the boy's genius, who fear that he may sink to mediocrity or suffer physical collapse unless his energies are conserved, and his talents developed through judicious training.

THE FIRES AT THE NEW YORK HOSPITAL FOR RUPTURED AND CRIPPLED.

On the evening of Sunday, January 29th, a somewhat serious fire occurred in the Hospital for Ruptured and Crippled, at the corner of Lexington Avenue and Forty-Second Street; but, by the pres-

ence of mind of the resident physicians and nurses, and the prompt and efficient services of the members of the Fire Department, all the children were gotten safely out of the building. Unfortunately, however, Mary Donnelly, the head cook of the establishment, who was in bed at the time, and whose presence in the house no one seemed to think of, was suffocated by the smoke that filled her apartment. During the next few days, strange to say, there were several other slight fires in the institution, all of which were quickly discovered and extinguished before any serious damage was done; and on February 2d it was found that these, as well as the more serious fire of Sunday evening, were the work of one of the patients, a bright and attractive little girl of eleven, who had been an inmate of the institution for nearly three years, under treatment for torticollis resulting from an attack of measles, and who had always been a special favorite among the other children and the attendants of the Hospital. On February 3d, the youthful incendiary was taken to the Yorkville Police Court and committed to the care of the Society for the Prevention of Cruelty to Children, to await the result of the coroner's inquest in the case of the unfortunate cook.

MEDICAL NOTES.

— In the *North American Review* for January, are printed a series of the autographs of Napoleon, written at various epochs in his eventful life. Starting in his earlier years with a bold and clear signature, it retains most of these characteristics in the days of his greatest successes; but parallel with the declining fortunes of the great man, is a degeneration of his autograph, until at the end we have nothing more than the rudest characterless scrawl. The autographs suggests to *Science* the ravaging changes in the nervous system that were the physiological concomitant of the turmoil raging in the hero's mind.

— "Doctor," said the patient, "I believe there's something wrong with my stomach." "Not a bit of it," replied the doctor promptly. "God made your stomach, and he knows how to make them. There's something wrong with the stuff you put into it, maybe, and something wrong in the way you stuff it in and tamp it down, but your stomach is all right." And straightway the patient discharged him. My! how a man does hate to have the doctor tell him the truth. How he hates to be told that he ought to be sick, and deserves to be ten times sicker than he is. — *Brooklyn Eagle*.

— Dr. William Osler tells the following interesting story to the *Canada Medical and Surgical Journal*:

"A young woman about twenty-eight years of age, well developed, of medium size, had had two previous labors, which were not difficult. She had expected her confinement in a week or ten days, and had got on the train to go to see her husband, who was working

'down the track.' Having a slight diarrhoea she went to the water-closet, and while on the seat labor pains came on and the child dropped from her. Hearing a noise and groaning, the conductor forced open the door and found the woman on the floor in an exhausted condition, with just strength enough to tell him that the baby was somewhere on the track, and to ask him to stop the train, which was running at the rate of about twenty miles an hour. The baby was found alive on the side of the track a mile or more away, and with the mother was left at the station where I saw her. She lost a good deal of blood, and the placenta was not delivered for some hours."

— The *Lancet* says that, according to the law of China, the punishment inflicted on the murderer of a father, mother, brother, husband, uncle, or tutor, and on traitors, is that appalling process known as *ling-chie*, or slow death. The fact that the crime has been committed under the influence of insanity procures no mitigation of the dread sentence, and the miserable culprit is sentenced to be cut into 24, 36, 72, or 120 pieces, a large proportion of which must be accomplished ere the executioner dares to touch a vital part, and end the torture of the victim. Only in certain cases does the Imperial clemency grant death after the eighth division. The commonest form of this penalty is that of twenty-four cuts; and the executioner prides himself on the anatomical skill with which they are administered. The victim being bound to a cross, the butcher by the first two cuts removes the eyebrows, by the third and fourth the shoulders, the fifth and sixth the breasts, the seventh and eighth the flesh of the forearm, the ninth and tenth the flesh of the arm, the eleventh and twelfth the flesh of each thigh, and so on.

—English exchanges comment with considerable severity on the fact that in virtue of a recent law forbidding the importation of contract labor, a trained nurse who had been engaged in London to take charge of the nursing department at the Pennsylvania General Hospital, was forbidden to land at New York, and was sent back by the next steamer, on the ground that her engagement constituted an infringement of the law. The same fate is probably in store for Dr. Heneage Gibbs, late of Westminster Hospital, who accepted an engagement as professor of Physiology at the University of Michigan. The local press, it is said, stimulated probably by disappointed candidates, or unscrupulous rivals, have lately called attention to the terms of his engagement with a view to putting the law in force should he venture out. It is well-known that this same law has been invoked to prevent the settlement of one or more clergymen called over from England. Surely this is protection run mad.

NEW YORK.

— A most extraordinary accident occurred at the Roosevelt Hospital on the first of February, when Charles McLean, a young Scotch patient, was fatally injured through the carelessness of the hospital order-

lies. He had had an abscess of the hip operated on, and, while still under the influence of ether, was removed from the operating-room on a roller stretcher. One of the orderlies in charge propelled the stretcher carriage, while the other went on ahead to open the door of the elevator-shaft in the hall. Having done so, he started the elevator from an upper floor, and, without waiting to see whether it had reached the operating-room floor, went away to attend to other duties, leaving the door of the shaft open. Unfortunately, however, the elevator still remained above, and the orderly with the roller stretcher pushed the latter into the open shaft: when the patient, with the canvas stretcher on which he was lying, fell headlong to the bottom of the shaft. He was found to have sustained a fracture of the skull, and died in about an hour, without having recovered consciousness.

—Through the good offices of Commissioner Brennan, of the Department of Charities and Correction, Dockstader's Negro Minstrel Troupe recently gave an entertainment at the female insane asylum on Blackwell's Island, which was thoroughly enjoyed by the 800 of the 1,600 inmates who were permitted to be present at the performance.

—On the 3d of February the Kings County Grand Jury, which has been investigating the management of contagious diseases in Brooklyn, read a presentment in which they express the opinion that the present system is inadequate to the needs of the population. They state that there is but one ambulance for the removal of small-pox patients, and one reliable man to perform the necessary duties, other than those of a physician, which the public safety demands. They believe that a regular and systematic weekly inspection should be made by the Health Board of the low-priced lodging-houses, by the distribution of the disease from which the recent epidemic of small-pox in the city was caused. Having recommended that an additional ambulance should be purchased, and that sufficient attendants be engaged to meet an exigency which might suddenly arise, they ask that a further appropriation should be made for the erection of a small-pox hospital provided with all modern conveniences for the successful treatment of the disease. The estimated cost of the erection and equipment of such a building is about \$100,000, while the amount at present in the treasury, at command for the purpose, is only \$20,000. Having urged that the new hospital be built as quickly as possible, though not within the corporate limits of Brooklyn, they conclude in the following words: "A municipality approaching a population of a million people—the third city in the Union and fourth English-speaking city in the world—should have such a complete health and sanitary system as at all times to inspire confidence that any outbreak of pestilence of any description can be taken care of, and not justifiably excite the alarm or timidity of its citizens."

—Dr. Griffin, the new Health Commissioner of Brooklyn, who went on duty the 1st of February, has already commenced an active campaign against the

small-pox prevalent there. He has detailed almost every physician employed by the city to this special duty, and has announced his intention to prosecute all medical men and others, who neglect to report cases of small-pox.

Miscellany.

DIABETES MELITUS IN AN INFANT.

DR. W. H. DEANE reports, in the *Medical Record*, the following case: "On November 20, 1887, a little girl, aged one year and three weeks, was brought to my office by her mother, who said that the child was somewhat fretful at night, seemed rather thirsty, rolled its head while sleeping, occasionally awakened from sleep with a sudden scream, and, she thought, was passing more urine than it should.

"The child was bright, fairly well nourished, with no marked evidences of any serious trouble. The child was, with some difficulty, cutting several teeth, and I considered the symptoms as due to that cause. The increased secretion of urine, which the mother had referred to, I thought very little about. In a very few days I was called to see the child, and found it in about the same condition as when at my office, except that it had begun to show some emaciation. I then asked for, and after some difficulty, on account of the extreme youth of the patient, obtained a specimen of the urine, which I found, by each of the copper, indigo, and fermentation tests, to contain a considerable amount of sugar—about ten grains to the ounce. I immediately began administering codia, and restricted all sugar from the diet. Nevertheless, emaciation rapidly progressed, digestive disturbances became more or less troublesome, the rolling of the head and crying out suddenly in sleep continued, and on January 4th the child passed into a well-marked condition of diabetic coma, and succumbed in twenty-four hours. Under my treatment the amount of urine diminished somewhat, although the specific gravity remained at 1040, and the sugar was continually present.

"The extreme youth of the patient, the rapidly fatal termination, and the continued presence of symptoms of brain-irritation, have caused me to regard this case as one quite singular."

MEDICINE vs. BAYONETS.

GENERAL SIR NEVILLE CHAMBERLAIN, of India, paid a very high compliment to the humanizing and civilizing effect of the Indian medical service in a recent letter to Prof. D. B. Smith, and showed that from a political point of view that service has been of the greatest value. He says:

"You are right in supposing that I have expressed an opinion that the peaceful and civilizing influence of the work done in the dispensaries and by regimental surgeons on the frontiers of India, has been in political importance equivalent to the presence of some thousands of bayonets. I have held this opinion, because no amount of military coercion or of purity of administration could have exercised the same pacifying effect on the heart of the nations that has been produced by the sympathetic care of and successful

treatment of diseases, many of which had been previously considered incurable. Throughout my service on the frontier of India I have never known a time when the halt, the lame, and the blind have not flocked into our cantonments or into our camps in search of relief from suffering; and, however distasteful may have been the sight of our soldiers, or however galling the idea of subjection to British rule, the people have come with confidence from far and wide to seek medical aid. The fame of the English doctors has spread beyond our frontiers into the remotest hills and glens, and the difficulties overcome and sufferings endured in order to reach a medical officer might seem incredible to those unable to realize what it is to be living under conditions devoid of medical and surgical aid.

"It is because of such unexpected philanthropy that, as conquerors, we hold a position in the minds of the people which would not otherwise be possible. The great question to be solved in the future is that of how to bridge over the chasm which separates the rulers from the ruled. The means of accomplishing this end may be mainly looked for in the sympathy to be created between the races; and I think the medical profession will always have it in their power to give most important aid towards the attainment of this object."

AN EXTRAORDINARY BRAIN INJURY.

The infliction of fatal injury to the brain by the thrusting of pointed objects beneath or through the upper eyelid, through the orbital plate into the brain, has occurred a number of times. The *Medical Press and Circular* after referring to the fact that baby-farmers have been known to procure the death of their charges by pushing needles in, and that not long since an irascible "fare" thrust his stick some four inches into the brain of a cab driver in the same way, goes on to describe a certainly remarkable form of brain injury. The effect of the sort of injuries above referred to is generally very prompt, and within an hour or two—even if not at once—serious symptoms manifest themselves. A curious exception to this rule was the subject of an inquiry recently at the London Hospital, the victim being a commercial traveller, thirty-two years of age. Until the last few weeks the deceased is stated to have been in good health, and to have kept a set of books most accurately. He was admitted into the hospital complaining of a pain in his head and feeling drowsy. On the 19th inst. symptoms of apoplexy (?) appeared, and he died a few hours later. On making a post-mortem examination of the brain, an abscess, the size of a turkey's egg was discovered at the base, evidently not of recent formation, inside of which was a penholder and nib, measuring altogether some three inches in length. This foreign body must have been in its position for some considerable time, it being embedded in bone. No trace of injury to the corresponding eye or nostril could be detected. The widow of the deceased had never heard him allude to any injury of the kind, and it is quite unknown how and when it was inflicted. The pen and nib were of the ordinary school pattern, and there is nothing to show that the injury was not inflicted years ago, when the deceased was at school. Altogether, it is a very remarkable case and demonstrates the extreme tolerance of the

brain to very serious injury and to the presence of a foreign body, under certain circumstances. It is fortunate, in one sense, that he died in a hospital; in private practice his death would have been certified as due to apoplexy, or, in case of an inquest, to "visitation of God."

THE HYPNOTIC ACTION OF BOLDIN.

It has been known for some time that the glucoside which is contained in boldo-leaves, and which is called boldin, had hypnotic properties.

Recently French physicians have been experimenting largely with the drug. Their results have been summarily stated by Dr. Juranville in an extensive work on the subject.

According to Dr. Juranville, as reported in the *Therapeutic Gazette* from his original article in *Le Progrès*, boldo, or the glucoside boldin, is superior to any other hypnotic or narcotic (such as chloral, opium, etc.). It is easily taken, and is unaccompanied by any disagreeable symptoms. Indeed, the author asserts that its use increases the appetite and greatly strengthens the patient. Doses of five to ten grammes (77 to 154 grains), have been given daily without causing any evil results. The sleep produced by the drug is similar to natural sleep in every respect; in this respect the drug is superior to all other hypnotics. The respiration becomes regular and quiet. Excited patients, suffering from hysteria and other nervous complaints, who for a long time have been unable to sleep, sank into a most refreshing and tranquil sleep, under the influence of boldin.

The amount of the glucoside contained in boldo-leaves is about three per cent.

The drug may be given in capsules, in doses of .2 gramme ($3\frac{1}{10}$ grains), or, as an injection, of 100 grammes of water ($3\frac{1}{10}$ ounces), and 5 grammes (77 grains) of boldin.

PERITONITIS ANTE-PARTUM.

A CASE of the above affection recently occurred in St. Bartholomew's Hospital, and is described by Dr. Gow in the *Edinboro' Medical Journal* for January, 1888.

The patient was a stout, well-made woman, aged thirty-two, who had had eight children previously, the labors in all these cases being natural. She was seen by the reporter for the first time on the morning of May 9th. She complained of frequent, sharp abdominal pains, not resembling labor pains in character. Her lips and cheeks were livid, and beads of sweat stood on her brow. Her tongue was slightly moist. There was frequent retching. The hands and feet were cold and clammy, and the pulse was barely perceptible at the wrist, and could not be counted. The respirations were rapid, being about forty to the minute. She was quite conscious, and complained of great pain on turning onto her left side. The abdomen was distended, and the fetus could be plainly felt, apparently within the uterine cavity.

Per Vaginam.—The cervix was soft, the os being dilated to about the size of a five-shilling piece. The membranes were unruptured. The head was felt to be presenting. As she complained of constant desire to pass water with inability to do so, a catheter was

passed, and about one and a half ounces of urine drawn off.

The history given by the patient was that one month previously her right leg slipped through a hole in the floor, nearly as far as the groin, owing to some rotten boards giving way. Since then, she says, she has never felt well. She had reached nearly the full period of gestation, and was expecting to be confined every day. She remained in fairly good health until the evening of May 8th. At 6 p.m. of that evening she was seized with sudden abdominal pain, and vomited. She was visited by one of the students, who found her complaining of abdominal pain and distension. She was belching up wind, but otherwise did not seem seriously ill. The pulse-rate was said to be then about 90. She was ordered some mild carminative.

Seeing the desperate state of the patient, it was decided to perform version, and remove the child as rapidly as possible. Before commencing the operation the patient's abdomen was rapidly auscultated, but the fetal heart could not be found. The patient was placed on her back, and version commenced. To subdue the resistance of her abdominal muscles a few whiffs of chloroform were administered tentatively; but, as it made the patient more cyanotic than before, it was discontinued. Just as the knee of the child had been reached the patient ceased to breathe. In the hope of saving the child an incision was made into the abdomen.

On opening the peritoneal cavity a large quantity of semi-opaque peritoneal fluid, containing flakes of lymph, escaped. There was no blood in the peritoneal cavity. The uterus was seen covered with flaky lymph. An incision was made into it, and the child extracted about five minutes after the death of the mother. The child's heart was not beating, and all attempts at artificial respiration failed. There was only slight hæmorrhage on cutting into the uterus. There was no blood in the uterine cavity. No evidence of rupture of the uterus or other organ was discovered. The inflammation of the peritoneum was most marked over the uterus and in its neighborhood.

No cause for the peritonitis could be found, but unfortunately no complete examination of the body was obtainable. Death took place fourteen hours after the onset of the symptoms.

In this case there is great difficulty in seeing any etiological connection between the history of the fall and the rapidly fatal peritonitis. The incompleteness of the post-mortem examination renders it impossible absolutely to eliminate various common causes of peritonitis, such as perforation of the vermiform appendix; but no ground of suspicion of any such cause was discovered.

The author cites three other cases of this rare affection, one from the writings of Sir J. Y. Simpson, and two from Matthews Duncan.

REPORTED MORTALITY FOR THE WEEK ENDING JANUARY 28, 1888.

Deaths reported 2,117; under five years of age 789; principal infectious diseases (small-pox, measles, diphtheria and croup, diarrhoeal diseases, whooping-cough, erysipelas and fevers) 127, acute lung diseases 440, consumption 275, diphtheria and croup 168, scarlet fever 64, diarrhoeal diseases 29, measles 20, typhoid fever 18, whooping-cough 17, malarial fever 14, puerperal fever 10, cerebro-spinal meningitis eight, erysipelas eight, small-pox four. From measles New York and District of Columbia seven each, Baltimore six. From typhoid fever Milwaukee three, New York, Brooklyn, Boston, District of Columbia, Charleston and Lawrence two each, Baltimore, Lynn and Somerville one each. From whooping-cough, New York six, Boston four, Brooklyn and Baltimore two each, Milwaukee, Lowell and Springfield one each. From malarial fever, New Orleans five, New York four, Baltimore three, Brooklyn two. From puerperal fever, Brooklyn and Milwaukee three each, District of Columbia two, Boston and New Orleans one each. From cerebro-spinal meningitis, Milwaukee and Somerville two each, New York, Worcester, Lynn and Springfield one each. From erysipelas,

New York three, Boston, Brooklyn, District of Columbia and Nashville one each. From small-pox New York three, Brooklyn one.

In the 28 greater towns of England and Wales with an estimated population of 9,398,273, for the week ending January 14th, the death-rate was 23.3. Deaths reported 4,194; infants under one year of age 835; acute diseases of the respiratory organs (London) 579, whooping-cough 508, scarlet fever 68, measles 60, fevers 17, diphtheria 33, diarrhoea 27.

The death-rates ranged from 14.2 in Sunderland to 34.9 in Manchester; Birmingham 24.6; Blackburn 27.6; Hull 18.3; Leeds 23.1; Leicester 15.3; Liverpool 21.0; London 23.6; Nottingham 22.6; Portsmouth 20.6; Sheffield 25.3; Wolverhampton 28.7.

In Edinburgh 25.8; Glasgow 25.1; Dublin 35.8.

The meteorological record for the week ending January 28, in Boston, was as follows, according to observations furnished by Sergeant O. B. Cole, of the United States Signal Corps:—

Week ending	Barometer.		Thermometer.		Relative Humidity.				Direction of Wind.		Velocity of Wind.		State of Weather.		Rainfall.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JANUARY 28, 1888, TO FEBRUARY 3, 1888.

PAGE, CHARLES, surgeon and lieutenant colonel. To be assistant surgeon general with rank of colonel. November 17, 1887.

McKEE, JAMES C., surgeon and major. To be surgeon with rank of lieutenant colonel. November 17, 1887.

GIRARD, ALFRED C., captain and assistant surgeon. To be surgeon with rank of major. November 17, 1887.

FISHER, W. W. R., first lieutenant and assistant surgeon. Granted leave of absence for one month on surgeon's certificate of disability. S. O. 4, Department of California. January 20, 1888.

RAYMOND, H. I., first lieutenant and assistant surgeon. Ordered to Fort Bidwell, Cal.

FISHER, W. W., first lieutenant and assistant surgeon. Ordered to Presidio of San Francisco, Cal. S. O. 25, A. G. O., January 21, 1888.

SOCIETY NOTICE.

NEW YORK STATE MEDICAL ASSOCIATION, FIFTH DISTRICT BRANCH II.—The next meeting will be the Fourth Annual Meeting, to be held in Brooklyn, on Tuesday, May 22, 1888. There will be a morning and an afternoon session.

EDWIN BARNES, M.D., President.
E. H. SQUIER, M.D., Secretary, P. O. Box 94, Brooklyn.

APPOINTMENTS AT THE CHILDREN'S HOSPITAL, BOSTON.

Dr. T. M. Botch has been elected Visiting Physician, Dr. H. L. Borrell, Visiting Surgeon, Dr. W. N. Bullard, Neurologist and Electrician, Drs. T. F. Sherman and C. W. Townsend have been elected Assistants in the Medical Out-patient Department.

DEATHS.

Died in Lowell, Mass., January 30, 1888, Joel Spalding, M.D., M.M.S.S., aged sixty-eight years.

Died at Whitinsville, Mass., February 1, 1888, Rowse Reynolds Clarke, M.D., M.M.S.S., aged sixty-five years.

Died at Wellesley Hills, Mass., January 31, 1888, Charles Warren, M.D., M.M.S.S., aged seventy-three years.

In Boston, Mass., February 2, 1888, George Stevens Jones, M.D., M.M.S.S., aged seventy years.

BOOKS AND PAMPHLETS RECEIVED.

Thirteenth Report of the Salem Hospital. 1888.

Remarks on the Recent Outbreak of Typhoid or Enteric Fever at Southampton, L. I. By F. E. Beckwith, M.D., of New Haven.

The Tympenic Kymograph: A New Pulse and Blood-Pressure Registering Apparatus. By Henry Sewall, Ph.D., Professor of Physiology in the University of Michigan. 1887.

The Rules of Aseptic and Antiseptic Surgery. A Practical Treatise for the Use of Students and the General Practitioner. By Arpad G. Gerster, M.D., Professor of Surgery at the New York Polytechnic. Illustrated with 248 engravings and 3 chromolithographic plates. New York: D. Appleton & Co. 1888.

A Synopsis of the Physiological Action of Medicines, Prepared for the Use of the Students of the Medical Department of the University of Pennsylvania. By Louis Starr, M.D., and James B. Walker, M.D., assisted by W. M. Powell, M.D., Third edition; Enlarged. Philadelphia: P. Blakiston, Son & Co. 1888.

Rectal and Anal Surgery, with a Description of the Recent Methods of the Hincutans. By Edward Andrews, M.D., LL.D., Professor of Clinical Surgery in the Chicago Medical College, etc., and E. Wyllis Andrews, A.M., M.D., Adjunct Professor of Clinical Surgery in the Chicago Medical College, etc. With original illustrations. Chicago, 1888.

A Contribution to the Study of Cysts of the Vagina, with the Report of a Case. By George Woodruff Johnston, A.M., M.D., Washington, D.C. Lecturer upon Operative Gynecology in the National Medical College; Director of the Woman's Clinic of the Central Dispensary and Emergency Hospital, etc. Reprint. New York: William Wood & Co., Publishers. 1887.

Suicide in its Relation to Insanity. By John J. Reese, M.D., Professor of Medical Jurisprudence and Toxicology in the University of Pennsylvania. Reprint. 1888.

Report of the New York Post-Graduate Hospital including the Babies Ward. Founded February 1, 1884. For the year ending May 1, 1887.

An Address from a Special Committee of the College of Physicians of Philadelphia to the Medical Societies of the United States: Concerning the Dangers to which the Country is Exposed by the Ineffectual Methods of Quarantine at its Ports, and in Regard to the Necessity of National Control of Maritime Quarantine, to which is Appended the Report of the Committee of the College of Physicians of Philadelphia Appointed to Investigate the Efficiency of our Quarantine Arrangements for the Exclusion of Cholera and other Epidemic Diseases. 1888.

TWO CASES ILLUSTRATING THE EFFECTS OF PRESSURE FROM POLYPI IN THE MIDDLE EAR.

BY CLARENCE J. BLAKE, M.D.

THE following cases, though simple in themselves and not uncommon, are reported because of the concomitant symptoms, as a larger growth in the upper portion of the middle ear, might have existed with no other indication of its presence than the usual objective and subjective symptoms common to polypi accompanying chronic purulent inflammation of the middle ear; though in the two cases here cited there were general symptoms of a grave character, until examination of the ear revealed the true cause of the disturbance.

The first case, that of a man forty-five years of age, was seen for the first time ten years ago, with two large polypi springing from the outer wall of the upper portion of the tympanic cavity, accompanying a purulent inflammation, a recurrence of that which was brought on by an attack of scarlet fever in childhood. These polypi were easily removed, the discharge from the ear soon ceased and did not recur until eight years later. This recurrence of trouble in the middle ear was neglected by the patient, who was a very busy man, until to the discomfort attending the sense of fulness, subjective noise, and offensive discharge from the ear, were added slight vertigo and a sense of numbness in the corresponding side of the face.

Under these circumstances the patient decided to again apply for relief, but on the night previous to his visit had a much more severe attack of vertigo and awoke in the morning to find himself with a well-marked facial paralysis.

Examination of the ear showed the external canal to be normal except for the excoriation due to the maceration of the skin by the discharge, which was free and purulent; there was destruction of the membrana tympani and the polypoid mass projecting downward from the upper and posterior portion of the tympanic cavity was evidently sloughing. The removal of this mass revealed a larger and more vigorous polypus which by itself constricted the one first removed, and in addition was exerting considerable pressure upon the incus, and upon the inner and posterior wall of the cavity. This growth being removed entire by the use of curved forceps, the middle ear cavity was thoroughly washed out with a weak solution of bicarbonate of soda by means of a middle ear syringe, the washing bringing away considerable masses of caseous pus, and macerated epithelium. After a careful drying the ear was dressed with boracic powder and stopped with cotton. The vertigo was almost immediately relieved and disappeared within six hours, and the face was entirely free from uncomfortable sensations and distortion at the end of three days. Subsequent treatment resulted as before, in a speedy cessation of the discharge, and the ear remained quiescent until a year later when there was a recurrence of the facial paralysis following a purulent discharge from the ear of three weeks' duration. In this instance the removal of the softer and more rapidly growing polypus entirely relieved the facial symptoms and the vertigo which accompanied them and which was very much less than on the previous occasion.

The second case was that of a woman forty-five years of age, who as the result of purulent inflammation of the middle ear following scarlet fever in childhood, had a large perforation in the posterior half of the membrana tympani, through which, when first seen five years ago, projected from above downward a small mucous polypus. This polypus was found to grow from the outer wall of the upper portion of the tympanic cavity posteriorly to the head of the malleus, its greater bulk being lodged between the outer tympanic walls and the body of the incus. The growth was removed by means of the curved forceps, and the subsequent treatment resulted in a speedy cessation of the discharge.

Two years later, following recurrence of discharge from the ear of three months' duration, the patient again came complaining not only of the return of the purulent trouble with its accompanying discomforts, but also of slight vertigo, accompanied by subjective noises in the ear, evidently of circulatory origin, both of which symptoms were increased by fatigue, over-exertion, or by the ingestion of anything which increased the circulation in the head. Examination showed a return of the polypoid growth, the removal of which relieved the vertigo and decreased the tinnitus. For a period of three weeks during which the discharge from the ear steadily decreased, the patient was under observation and this time, while there was slight constant circulatory tinnitus, there was no vertigo except under the especial conditions before mentioned. Following this period of three weeks the patient was not seen by the writer until three months later by which time the discharge from the ear, which had again occurred, had become very copious. The vertigo, before occasional had become constant, and the tinnitus very distressing, indeed, the vertigo was so much increased by any movement of the head, especially toward the right side with the body erect, that the patient considered herself confined to bed. Any movement of the head, or even the arms and upper part of the trunk not only increased the dizziness, but superinduced nausea so that food had been retained with difficulty for a period of over forty-eight hours.

The general condition indicated considerable prostration, the surface of the body was cool, the pulse was small and weak at the wrist, the face pinched and wearing an expression of anxiety. In addition to the discomfort due to the sense of fulness in the ear, the vertigo, nausea and tinnitus, there was complaint of pain referred to the corresponding parietal region and to the depth of the ear. Examination of the ear showed a repetition of the conditions previously observed, the polypus, however, being very much larger and firmer than on previous occasions. By means of the curved forceps the growth was removed piece-meal, its whole volume equalling a sphere about six millimetres in diameter.

The condition of the patient and the increase of the vertigo attendant on the use of the forceps, necessitated much deliberation in the removal of the growth, and frequent pauses for intervals of rest; the greater portion of the growth however being removed in half an hour. One hour later the nausea had decreased and the vertigo was very much lessened. Forty-eight hours later the vertigo increased and was again relieved by a thorough cleansing of the upper and posterior part of the tympanic cavity by means of the

middle-ear syringe, Dr. H. L. Morse who made the three subsequent visits reporting the removal of considerable masses of macerated and swollen epithelium, the usual sequence of the presence of polyp in this region of the tympanic cavity.

Three weeks later the patient was able to be out of the house, there was a very slight purulent discharge only, and no vertigo even on sudden rotation of the head.

In both of these cases a growth between the outer tympanic wall and the incus projecting downward and pressing upon the long process of the incus as well as upon the body of that bone resulted in a permanent degree of pressure upon the labyrinth through the fenestra ovalis. In the first case, also, the location of the growth was such as to press upon that portion of the wall of the middle ear which separates that cavity from the canal of the facial nerve.

As has been shown by Gruber, there is a certain proportion of cases in which there is a dehiscence of bone in this portion of the facial canal, and while it is impossible to substantiate the fact in this particular case, the explanation is at least permissible that the pressure of the growth upon a membranous wall communicated sufficient pressure to the nerve to result in a temporary suspension of its function. In support of this supposition is the fact of the ready recovery from the facial paralysis after the removal of a tumor the pressure of which was probably of short duration, and the repetition of the similar experience in the same case may be taken as confirmatory of this view.

In the second case, the pressure of the growth upon the incus and so upon the stapes and labyrinth was in itself so slight as to be insufficient to cause irritation of the semi-circular canals and subsequent vertigo, which symptoms appeared only when there was added to this pressure the pressure of an increased intralabyrinthine circulation.

In the last recurrence of the trouble, however, the greater pressure due to the larger mass was sufficient in itself to cause the vertiginous and other reflex symptoms, the speedy relief following the removal of the growth being a sufficient evidence of the truth of this proposition.

As has been said, these cases are reported not because they are uncommon but because of the direct evidence of cause and effect, and because of their possible interest to the general reader.

A CASE OF CEREBRAL LOCALIZATION, WITH DOUBLE TREPHINING (ACQUIRED SPASTIC HEMIPLEGIA — PORENCEPHALUS).¹

BY W. N. HILLARD, M.D.

GENTLEMEN: The case which I have the honor to report to you to-night derives its chief medical interest from the fact that the diagnosis of the lesion, and the localization of its seat were correctly made during the life of the patient, and that the latter was such as could be easily reached by a comparatively simple operation. Cases of operative interference in congenital cerebral lesions, or in those occurring in the earlier months of life, are very rare, and I, therefore, believe it of importance that the possibility of localizing these lesions, and the probability that in certain cases, even though they be incapable of cure, their

results can be mitigated, should be strongly emphasized. Until of late years, but little attention has been paid to the various forms of congenital or infantile cerebral lesions, excluding hydrocephalus and inflammations of the meninges. Patients suffering from congenital or infantile cerebral paralyses are too often considered not only absolutely incurable, but incapable, even, of improvement. Some cases unquestionably are so; but, on the other hand, I believe that in many of this class of cases we can do much to improve and mitigate those symptoms which we cannot remove, and there is no doubt that a broad field lies open here for cerebral surgery, provided, only, that the neurologist can state with some degree of precision the condition existing within the cranium, and, if the lesion be a localized one, point out its seat.

The present case occurred in the service of Dr. Bradford, at the Children's Hospital, and it is through his kindness and at his suggestion that I bring it before you to-night.

The patient was a boy, four and a half years old. There was no history of any nervous disease in the family, and no history of the patient was obtainable, except that he was supposed to have been in his present condition since birth. The delivery was by forceps, and the child had a scar and depression over the right parietal bone, supposed to have been caused by them. There was no history of convulsions at any time. The child was brought to the Hospital by his parents, who insisted upon an operation — trephining over the depression — although they were informed that there was little hope of improvement from what they desired, and still less of cure. This operation had been decided upon before I saw the child.

I first saw the patient in the Hospital on the 22d of June, 1887, when his condition was as follows:

The child was seated in bed. As a rule, he sits quietly all day, doing nothing. Expression vacant. Intelligence limited, although he has a certain sense of his surroundings, as was shown by his screaming one day when he was placed in a bed in another part of the ward, and pointing with his finger to the old one, and continuing this until he was replaced. He understands simple words and sentences, and obeys simple directions. He signifies when he is thirsty. When told to do so, he will turn his head, and he will hand an object to a person, or smell of a rose, when it is suggested to him. He can say "yes" and "no," and will say "good-bye" when any one is going away, but he cannot talk. He drudges constantly.

Physical condition: Well nourished, well developed. Head large, rather square. On the right side, 5 cm. behind, and about 4 cm. above the upper edge of the anterior border of the pinna, there is a scar 5 cm. long, extending forwards and slightly upwards. This scar lies in front of the occipito-parietal depression, which is alike on both sides, and seems to cross the temporal ridge of the parietal bone, and the squamo-parietal suture. On palpation, there is an irregular knob or prominence under one portion of the scar, and a depression with irregularities on each side; that is, anteriorly and posteriorly. There is no decided tenderness here or elsewhere about the head. Nothing else abnormal was detected about the cranium.

All the special senses appear normal. There is right internal strabismus. Eyes not examined ophthalmoscopically.

¹Read before the Section for Clinical Medicine, Pathology, and Hygiene of the Suffolk District Medical Society, January 11, 1888.

Nothing abnormal could be detected about the trunk or organs of the thoracic or abdominal cavities. There was an occasional reduplication of the first sound of the heart.

The spine was straight; no tenderness in the back. The patient cannot use any of his extremities, but he uses those on the left much better than those on the right.

Upper extremities: The right upper extremity can be moved somewhat, but is never used. It is in a condition of spastic paralysis. The forearm is held semi-flexed upon the arm, and there is considerable resistance to passive motion, which can, however, be overcome after a time. The hand is firmly flexed on the forearm. He will not grasp anything with the right hand. He moves the left upper extremity much better than the right, and always grasps objects with the left hand, and then holds them firmly.

Lower extremities: The right lower extremity is smaller, and possibly colder than the left. There is a spastic condition of the knee and ankle. The foot is held flexed in the equinus position, with the toes pointing downwards. Some movement of the limb, however, is possible. He can flex at the thigh, knee, and ankle when he wishes. The left lower extremity is somewhat weak, perhaps from disuse: otherwise, nearly normal.

Knee-jerk exaggerated on both sides. Patient is unable to walk or to stand without support. He can take a step if supported under the arms, and he can hold his weight on the left leg. If the legs become locked at the knees, as they tend to do, he can support a portion of the weight of his body upon them. The sensation is apparently normal everywhere throughout the body. Nothing else abnormal detected.

To resume the case in short, we have here a boy, four and a half years old, with much diminished intelligence, inability to speak, inability to use any of his limbs well, and with right internal strabismus and right spastic hemiplegia. In addition, there is a well-marked cicatrix and depression in the right posterior parietal region.

After examination of the case, it was decided, at my suggestion, that in addition to the operation already proposed, the cranium should be opened over the cortical motor area of the left side, as this seemed to offer the strongest prospects of relief.

The operation was, accordingly, performed on the 27th of June, by Dr. Bradford. The patient being etherized, the various points were localized on the shaven head, and the position of the fissures of Rolando determined as carefully as possible. Dr. Bradford trephined first on the right side of the head, directly over the cicatrix. A curved incision with its convexity downwards, about six inches in length, was made through the scalp, the periosteum was removed intact, and the cranium trephined—the trephine used being an inch in diameter. The outer table of the portion of bone removed showed a fracture, and the inner a slight inequality, due to a fissure. The dura mater exposed was thickened, and its vessels filled with blood. It (the dura mater) was then incised, and the brain and pia exposed to view. There was no evidence of pressure, nor of anything abnormal here below the dura. The brain protruded slightly through the opening and pulsated. [It is important to note here the fact that, in spite of the fracture of the cranium, and the accompanying thick-

ening of the dura mater, the pia and brain were, as far as could be told, absolutely normal.]

It was now decided that it would be wise to trephine over the probable seat of the lesion on the left side, and, at Dr. Bradford's request, I located the motor area on the left side, where it was presumable, from the symptoms, that the lesion would be found. This point was a little higher and slightly further forward than that trephined on the right, at the junction, as nearly as could be determined, of the middle and lower thirds of the fissure of Rolando. There was a very small superficial cicatrix in the skin here, not involving the deeper tissues of the scalp, and which had remained undetected until the position was marked. An incision similar to that made on the right side was now made here. The cranium, when uncovered, appeared perfectly normal. It was trephined, and, on the removal of the bone to which the dura was attached, a depression in the brain substance—porencephalic cavity—was exposed. This not only occupied the whole space directly under the opening, but also extended somewhat anteriorly. The pia seemed to be adherent. The brain substance in this depression, which was estimated as about $1\frac{1}{2}$ inches long, by $\frac{3}{4}$ inch wide and $\frac{3}{8}$ inch deep at the deepest part, was puckered and shrivelled. Considerable haemorrhage from the bone followed the removal of the button on this side. This was quickly controlled by plugging.

As the patient's condition was poor—pulse very weak, and respiration slow and labored—nothing further was attempted. After replacing the buttons of bone on each side, and stitching the dura mater on the right, the incisions were sewed up, and bandages and dressing applied.

The patient, however, never rallied thoroughly after the operation, although he recovered consciousness in the evening, and was conscious until the following morning, when he died at 10 A. M., about seventeen hours after the operation. The temperature was not taken on the evening following the operation, but, the next morning, rose to 105°. There was no autopsy.

This case, it seems to me, illustrates some interesting points. In the first place, it demonstrates the possibility of localizing lesions of this character (porencephalic) in children in certain cases. This is, of course, the first step in any rational attempt for their direct alleviation or cure. That these lesions can be localized with moderate accuracy, at least, sufficiently for all practical purposes in a large proportion of the cases of this class, I am convinced, and I believe it to be the duty of the neurologist, so far as lies within his power, to improve and perfect his knowledge, so that, when appealed to by the surgeon, he shall be able to point out where the instrument should be directed, and to state what sort of lesion is likely to be found.

Secondly, I believe that this case may be accepted as evidence that these lesions—many of them, at least—can be reached by surgical interference without serious difficulty, since simple trephining can no longer be regarded as a serious operation in ordinarily healthy persons. If this be true, its importance is at once manifest. If these lesions can be localized, and if surgical interference in them is not a matter of serious difficulty, nor of marked risk to the life of the patient, we have here, at least, one expedient which offers a prospect of alleviation in these cases, however remote.

It is well known to most of us, but I repeat it here

for the sake of emphasizing it again, that there are no cases which, as a class, are regarded by the whole medical profession as more utterly hopeless and as more entirely beyond any possible medical aid and assistance than congenital and infantile brain affections. There is no class of cases in which the patients are more utterly useless to themselves and to the world, or more of a burden to their parents and relatives. Anything, therefore, which affords the least prospect of relief is, in them, of the utmost importance.

There are two other points in this case which are of both neurological and surgical value, which I will refer to in short.

The first is the question of the advisability of trephining in more than one place at the same time in children. Whether, in this case, the result might have been more favorable had the operations been performed separately, it is impossible to decide; but, in a similar case, it would certainly seem more safe to perform two operations.

The second point is one which, although theoretically well known, cannot be repeated too often, and it is well illustrated here. This is, that in spite of a fracture or visible injury on one side, the actual cerebral lesion may be upon the opposite, whether produced by direct violence or by *contrecoup*. Therefore, in case of cerebral injury, if the symptoms point to a lesion on the opposite side from the trauma; for example, if the hemiplegia is on the same side of the body as the fracture of the cranium, we should not trephine at the place of fracture, but on the other side.

In the case of our patient, the probability is that the whole trouble was traumatic, and due to the pressure of forceps. While on the right the parietal bone was fractured, on the left, the bone being more yielding, or the blade being in a slightly different position, or for some other reason, a different effect was produced. This was probably the rupture of the ascending parietal artery or one of its branches.

PROTRACTED GESTATION.¹

BY JOHN G. BLAKE, M.D.

The question as to whether gestation is really protracted beyond the normal period, is one upon which authors differ widely. Some of the most respected writers upon obstetrics, like Barnes and Tyler Smith, deny it entirely, claiming that the uniformity of nature's law is not violated in this respect, and that apparent exceptions spring from mistakes in date, or delays and interferences with the processes of conceptions by conditions which are out of our power to detect, prevent or control. On the other hand, Montgomery, with many other very high authorities, takes the opposite view. He believes there are exceptions to all rules and laws, and claims that there is no good reason why the subject under consideration should be exempted. He quotes Lord Spencer and Tessier's observation on cows, showing a variation of 81 days between the longest and shortest gestation, and an extension in some cases of 31 days beyond the normal period. Of mares the same facts are recorded, and instances given. These observations extend to many others of the lower animals with similar results. Montgomery also supports his theory of exceptions by reference to

the subject of dentition; instancing the fact that while the average time for first dentition is about four months, it is sometimes extended to a year, and children are sometimes born with teeth.

Since the normal duration of pregnancy is the rule, while the other is the exception, testimony in its favor should always be allowed to have great weight. The possibility of motives for misrepresentation, pecuniary or otherwise, must also be taken into account. This normal duration is from 275 to 280 days. My plan is to date conception from the fifth day after cessation of menstruation, and to count nine calendar months from that time. Experience has proved that this average is fairly accurate, although in no single case can I predict the beginning of labor within several days. In pregnancies dating from a single coitus, 275 days is, I believe, nearer the exact period of gestation.

Whether the condition of pregnancy is really or only seemingly prolonged, it is probable that every member of this society has at some time suffered from the inconvenience and anxiety attending such cases. When, as often happens, they occur in summer, and the detained M.D. sees his vacation slowly vanishing, with but little else to do than think of his case, it requires more than ordinary philosophy to avoid excessive waste of nerve tissue from annoyance. Thrice during the past fifteen years, has this been my experience. At other times I give the subject but little attention, and have no doubt from a general glance backward, that several other cases could be cited.

The first case was that of a multipara pregnant with her eleventh child. Her family went to a seaside resort twenty-two miles from Boston, early in May. I was requested to take charge, with the assurance that she always knew to a day, from past experience, when a physician's service would be required. The 10th of June was the latest date. I began to travel toward this point every afternoon, having promised to stay a few nights preceding the time at my patient's house. I continued to travel until July 4th, when either patriotism or gunpowder acted as the final stimulant, after a lapse of twenty-four days.

The second and third cases occurred during the past summer. Mrs. — engaged me to attend at her second confinement. Menstruation ceased September 18th. I made a date for June 26th, which would allow four days after cessation of menstruation. I waited until August 29th; about nine weeks later than the appointed time. During this period, a closer inquiry into facts revealed a mistake of a month in the lady's calculations; but even allowing this, the case exceeded the normal duration of pregnancy by five weeks. Some of the attending circumstances were of a painful character. The first baby, a girl of sixteen months, was attacked with diarrhoea. Removal to the seashore, with the kind and skilful care of a member of this society restored her. The parents desired to have the child where it could occasionally be seen by the mother, so it was transferred to a large airy house on the top of Mount Pleasant. Four weeks afterwards it was again attacked with a dysenteric diarrhoea. As the mother was now hourly expecting confinement, she was not willing to allow the child to be taken where she could not see it. Treatment in the city was not successful, and the baby died after a week's illness. I have never felt quite satisfied that the child could not have been

¹ Read before the Obstetrical Society of Boston, December 10, 1887.

saved, had circumstances permitted its removal again to the seaside. The nervous excitement attendant upon this, no doubt helped to complicate the mother's case.

The third case was that of a young German Jewess, a primipara whose labor came on thirty-five days after the expiration of the normal period of utero gestation. The labor was tedious in this case, and delivery was finally effected by forceps. The child was large and healthy, and somewhat disproportionate to the small size of the mother, weighing ten pounds.

Dr. W. H. Lincoln, of Millbury, Mass., sends the following well authenticated case, where the testimony seems conclusive that gestation was prolonged four weeks. Mrs. —, twenty-two years of age; rather below medium height; weighed about one hundred pounds; had always been very regular, catamenia occurring every twenty-eight days and lasting four or five; never had borne children; was last unwell June 15th, remaining so during four days as usual; expected to be confined March 19th; during 18th, 19th, and 20th March had some pain and very slight "show." These symptoms disappeared, however, and she was about the house, walking and riding out until April 15th, when she was taken in labor which lasted forty-eight hours. She was then delivered by craniotomy of a male child, the remains of which weighed eight pounds two ounces. The head was ossified to such an extent, that very little if any motion could be detected at sutures.

In the first and second cases reported delivery was natural, and the size of the children relatively to the mothers, not unusually large. All the infants were strong, well formed and vigorous; but while the heads were shapely and firm, and the bodies finely developed, I cannot say that they were better in these respects than others, in whom no suspicion of protracted gestation existed.

In looking for the causes of these and similar phenomena, I find the following among others assigned: Delay of the ovum from its seat in the ovary along the fallopian tube to cavity of uterus;² the ovulum may lie at a greater depth in the substance of ovary, which may have had its texture thickened or indurated by effect of previous inflammation. A similar change may have taken place in the proper coat of that body, or in its peritoneal investment, which will still further delay the escape of the ovum, by resisting the natural tendency to open under increasing distention, and by rendering a longer time necessary for the accomplishment of requisite absorption. The tube may have formed adhesions with the ovary, or with other parts, in its course to the uterus; or, by having its natural diameter contracted, may be incapable of transmitting the ovum without delay. A defect in the due preparation of the decidua nidamentum will cause similar trouble. Changes in the mucous membrane of the uterus are also supposed to cause delay. Some authors attribute protraction to advanced age, repeated impregnation, male sex in the child, or irregular menstruation. Health and activity of the uterus may lead to postponement. A woman who menstruates every thirty days, is supposed to carry longer than one whose regular period is twenty-eight. Latency is another cause.

Fecundation does not always take place at exact date of coition. Hours or days may elapse after insemination, before spermatozoa come in contact with

ovum. This is confirmed by Marion Sims who discovered spermatozoa in the cervical canal six days after intercourse. Professor Flint, Jr., saw them "in motion on the surface of the ovary eight days after" and "Dr. Perry discovered them alive in the mucus issuing from the os uteri eight and one-half days after the last coitus."³ Heredity is supposed to cause irregularities at times.⁴

In a calculation made by Dr. Merriam, from 114 cases, counting from last day of menstruation to birth, the following were the periods: In the 37th week, 3; 38th week, 13; 39th week, 14; 40th week, 33; 41st week, 22; 42d week, 15; 43d week, 10; 44th week, 4. From these results he considers that in the greater number of women gestation is completed in the 40th week after the cessation of menses.

Harvey quotes a case in which a woman carried her child more than sixteen months, during ten of which she felt the movements of the foetus.⁵ Dr. Henderson reports one in which a multipara thirty-five years of age had given birth to her former children with no unusual symptoms; in this particular case the date from last catamenia to birth was fifteen months. The child was born dead, but was alive three hours before delivery; weight sixteen and one-half pounds.

Case of Dr. E. N. Lewis, reported by Dr. Munde: Menstruation ceased August 28th; coitus two days after; symptoms of pregnancy within ten days (morning sickness, etc.); quickening at four and a half months; expected confinement on June 7th, but it was delayed until August 8th. The child had a firmly ossified head, rather small; fontanelles entirely closed. From date of last menstruation to August 8th, gives 341 days.

Dr. Chamberlain relates a case. Quickening October 20th; confinement expected in first week of March; delayed until May 6th; child showed evidence of prolonged gestation. Posterior fontanelle entirely closed, and anterior fontanelle to a considerable extent; skin was thick and white and had lost its reflex character, and the child possessed a certain co-ordination of movements never seen at term.⁶

Velpeau records the following: Quickening at four months; symptoms of labor occurred at end of ninth month, but were suspended, and did not return for thirty days. He considers gestation to have extended over 310 days.

Among other cases are these from the *American Journal of Obstetrics*, Vol. XII:

Dr. Simpson, England, attended a case in which he believes gestation to have been protracted to the 314th day from cessation of menses. He thinks that in three other cases which came under his notice the terms were prolonged respectively 319, 332 and 336.

Meigs claims to have had a case where 420 days elapsed between conception and labor.

Bartholin reports that of a woman of Leipzig who was delivered in the sixteenth month.

M. Rigands gives a case in which a second mature child was born four and a half months after the first; an autopsy revealed a single normal uterus.

A history is given of an Italian woman who gave birth to a couple of infants apparently of mature development, one born three months after the other.⁷

⁷ Montgomery. Signs and Symptoms of Pregnancy, pp. 424, 431.

Dr. Hamilton speaks of a case that he delivered three times artificially with success, after the tenth menstrual period was passed.

The following synopsis is given in Taylor's "Medical Jurisprudence":

Dr. Murphy fixes the maximum of duration yet known at 324 days; Dr. Meigs, at 325; Dr. Bentley, at 291; Dr. Reid, at 293; Dr. Skey, at 293; Dr. Macilum, at 293; Dr. Ashwell, at 300; Dr. Steathy, at 298; Dr. Power, at 325; Mr. Chattaway, at 330; Dr. Duncan, at 300.

Mr. Duncan gives a case of first pregnancy of 300 days duration, second and third cases each 285 days, and a fourth 325 days, all in the same woman. Atlee gives two cases lasting 365 days.

There are some legal aspects of the subject which may be of interest. In England the period of gestation is not fixed by law. By some authorities 40 weeks or 280 days are allowed; by others, 43 weeks or 301 days are given as a limit.

In the United States, a decision in favor of paternity has been made in a case where gestation extended to 45 weeks and 2 days.

Legitimacy was disallowed in England where pregnancy was protracted to 44 weeks and 5 days.

In Germany it is laid down that gestation may be prolonged to 301 or 308 days, but not beyond that time. The general law of Germany places the period for ordinary gestation among women not married, at 285 days; but for a married or divorced woman, or a widow it allows 302 days.

In France legitimacy is allowed within 300 days; in Prussia, within 302 days; in Scotland, not after the tenth month.

Hohl, who records these facts, thinks that there is injustice in any fixing of rules regarding time; and advises that in exceptional cases a period of from 322 to 336 days should be admitted. It is more reasonable to leave the question open than to assign any arbitrary limit, to which there must necessarily be exceptions now and then. His reasons for so thinking are: (1) The ripening of the ovum in the ovary does not take an equal time in all women. (2) The ripe ovum does not always leave the ovary at a fixed time. (3) Coitus is not always effected at the time when the ovum lies ready for fertilization, which may be shortly before or immediately after menstruation. (4) The spermatozoa may meet the ovum in the uterus, or tube, or upon the ovary, and each will make a difference in time. (5) All fetal life does not mature at an equal period. The effect of these irregularities upon the child, does not seem to have been generally noticed, and this may be taken as evidence that its condition at birth is not materially changed. In the reports of cases referred to in this paper, very few of the children are spoken of as exceeding the normal size. One or two monsters are alluded to; and the case of Dr. Henderson where the child weighed sixteen and one-half pounds, is an isolated one.

This very fact of the non-increase of the child, seems to me one of the strongest arguments against the extension of gestation beyond the normal period. It is hard to imagine that with all the conditions favorable to continued increase, growth should stop at an arbitrary date, — yet this is what we are to infer from the reports. With gestation prolonged from two to sixteen weeks, the labors are not spoken of as difficult, except in a single instance.

Of course where no evil results are apparent, there is little to recommend in the way of treatment. We can imagine occasions, wherein the induction of labor at the expiration of the ten lunar months, might be called for, and would be quite justifiable. Hydrocephalic monsters, cases like that of Dr. Henderson, and others where the life of the child might be imperilled would certainly justify such measures. Personally I would feel no hesitation in interfering.

In conclusion, I must apologize for the unsatisfactory character, and lack of practical value, of this paper. The subject is a curious and interesting one; but the only well established fact connected with it as yet seems to be that there really is very little known about it.

My thanks are due Messrs. Foote and Morrison, house-officers of the City Hospital, for valuable assistance in the preparation of this paper.

SIX CASES OF UTERINE DISPLACEMENTS TREATED BY SHORTENING OF THE ROUND LIGAMENTS, WITH REMOTE RESULTS.¹

BY CHARLES F. STRONG, M.D.,
Physician to Out-patients at Jackson-Street General Hospital, Assistant Surgeon Free Hospital for Women, Assistant in Gynecology, Harvard Medical School.

THE operation to which the attention of the Society is invited this evening ranks as a comparatively new one, and has not, as yet, a definite value assigned it; a result largely due to the insufficient lapse of time that has been allowed between the performance of the operation and the reporting of the cases. It has its earnest advocates and equally vigorous opponents. I do not propose to burden you with anatomical details or facts, except such as have arisen in my own experience and the deductions which I have drawn from my own series of cases.

To avoid repetition I will give in detail the procedures I have followed in all my cases. I have aimed to make the operation as thoroughly aseptic as a laparotomy. I make an incision directly upon the spine of the pubis and locate the external opening of the inguinal canal, clearing away the edges of the ring, raise the little mass of fat lying just inside, and separating it by director and knife from the sides of the canal, draw it out until the round fleshy-looking fibre of the round ligament appears; exercising great care not to separate the proximal end of the ligaments from its fastenings. The fullest development of the ligament is not reached until an inch or more is drawn out. I free two or three inches of the ligament in this manner, handling it with great care and similarly treat the ligament of the other side. An assistant then lifts the uterus, vaginally, to its proper level and position, and any further slack of the ligaments is drawn out, and secured to the pillars of the ring by fine silk sutures.

The surplus mass of the ligaments is then folded upon itself and packed away, forming a plug in the ring, and the external wound closed without drainage. Dry occlusive dressing is applied, which is left undisturbed a week. A support inserted that will retain the uterus in its proper place and take all strain from the ligaments. The patient kept quietly in bed for two weeks.

CASE I. Mrs. C., multipara, forty-two years old.

¹ Read before the Obstetrical Society of Boston, January 12, 1888.

The patient had been under my care since 1852 with rectal disease, which I found to be due to prolapse of the uterus, and temporarily remedied by pessaries. The uterus, which measured three-and-one-half inches, was anteverted, and so imperfectly sustained that any support that prevented its sagging between the lateral bars was necessarily of such size or shape to incommode the patient and not infrequently cause erosions in the vagina. When wearing no support, the patient complained of constant pain through the rectum being often confined to bed by it. The first of August, 1886, I operated in the manner described above. Three-and-one-half inches of ligament were drawn out and secured on each side. There was no material difference in the size of the ligaments. A suitable pessary was adjusted, which was worn two months without inconvenience, then permanently removed.

The patient has been examined from time to time, the last examination being made January, 1888, one year and five months from date of operation. I find the uterus occupying as high a place in the pelvis as immediately subsequent to the operation. The patient is cured.

CASE II. Miss K., age twenty-eight, single. Chronic retroversion and retroflexion without adhesion. Symptoms: Backache and pain in both iliac regions; inability to stand. This patient had been under my observation for three years, during which time she had worn various pessaries, each of which afforded relief, but each of which also caused erosions in the posterior cul-de-sac of the vagina so that their use was intermittent and unsatisfactory. I operated in April, 1887, in the usual manner. There was a great deal of difficulty experienced from the thickness of the abdominal walls. I find in January, 1888, the uterus in perfectly normal position. The patient has been working as cook in a large hotel, and has not the slightest return of her old symptoms.

CASE III. Mrs. S., aged forty-five years, multipara. Referred to me in May, 1887, by Dr. W. L. Richardson. She had prolapse, the cervix just appearing through the vulva; areolar hyperplasia of uterus; and bilateral laceration of the cervix; rectocele, and cystocele of small size.

The symptoms were backache, attendant upon walking. I first repaired the cervix and on June 1, 1887, the eighth day subsequently, operated as described above for shortening the round ligaments. On the first of January, 1888, I found the uterus in its normal position and decreased in size to less than three inches. There was no rectocele, very slight cystocele. No longer any complaints of pelvic symptoms.

CASE IV. Mrs. S., aged forty-five, referred to me by Dr. W. L. Richardson. Prolapsus, lacerated cervix, rupture of perineum through sphincter, and of recto-vaginal septum. Rectocele and cystocele. The cystocele was covered by an immense ulceration from friction between the thighs.

I repaired the cervix and perineum in April, 1887, keeping the patient under observation for two weeks after she was about. The uterus stayed nicely in place, but in May she returned with prolapsus as complete as before. The newly-made sphincter was perfect, but the so-called "perineal body," had completely flattened out. July 4th I operated for shortening the round ligaments. Seven inches of ligament on each side were drawn out before the uterus was fixed in its proper position. The rectocele disappeared,

but the cystocele though improved, was not removed; on separating the vulva, a knuckle of the anterior vaginal wall was seen protruding. The patient was examined at intervals of a month with uniformly satisfactory results. The middle of December the uterus was found perfectly in place, the cystocele unchanged. Six-and-a-half months having now gone by, during which the patient had performed the usual household tasks of a poor woman, I felt justified in considering the operation a success, but to avoid any possible error, on January 2d, I again examined her and found the position just as bad as before, the uterus procident; lying entirely outside the vulva, with a large ulcer upon it from friction. The patient said it came down without warning, and not in consequence of any unusual strain, within a few days of her previous visit.

CASE V. Mrs. M., aged thirty years, multipara. Retroflexion and retroversion of uterus, prolapse and enlargement of right ovary, prolapse left ovary. Parametric inflammatory adhesions. Symptoms: Backache, constant bearing-down pains in the pelvis that prevented locomotion. Recurrent attacks of pelvic inflammation.

The patient had been under my care for more than a year, during which time she had the routine treatment, including many and various-shaped pessaries, which rendered her condition somewhat more endurable than when they were not worn. But the ovaries were an obstacle that prevented constant use of any pessary. From my notes, I find that no one form of support afforded relief beyond the period of one month. She was desirous of any operation that afforded a hope, however remote, of relief.

In the operation, performed June 28, 1887, I had the pleasure of assisting Dr. H. H. A. Beach, through whose courtesy I include the case among my own, as, except the immediate operation, the patient was entirely under my charge. The operation was performed in the usual manner, except that the two incisions were prolonged until they met in the median line, just above the pubes, and the ligaments were brought across the space, thus exposed and stitched to each other. The patient has been greatly relieved, not cured, nor do I expect her to be until the inflammatory exudation on the right is gone. All she suffers from now is pain of a neuralgic character, which affects the right side only. She takes plenty of exercise, and is vastly improved in general health. Anatomically, the operation has been a success. The uterus is in normal position, the ovaries are no longer prolapsed, and there has been a diminution of, at least, one-half in the enlarged ovary. The patient was examined the last of December.

CASE VI. Mrs. R., age, sixty-eight; multipara. Prolapsus, uterine between the thighs, and ulcerated; rectocele and cystocele. Symptoms: She declared the prolapsus was brought on by falling down stairs, and, as she had visions of securing damages, I have attached no value to subjective statements.

I operated November 1, 1887, in the usual manner. An abdomen, pendulous with fat, added greatly to the difficulty of the operation, and the ligaments were unusually adherent to the walls of the canal. Convalescence was modified by the patient removing the dressings in a few hours, and rubbing her dirty hands over the wounds, and by daily repetition of the offence, so that, for the only time, I failed of complete union by first intention. Every stitch-hole was an outlet for

pus; also, the patient got out of bed and walked about at the end of a week, and was thoroughly unmanageable. Still the ligaments held, and when I examined her, a week ago, the uterus was held high up, and then, two months after the operation, seemed firmly in place. With vulva opened, expulsive efforts showed cystocele and rectocele still present, but not protruding.

No. of cases.	Disease for which Operation was Performed.	Immediate Result.	Remote Result.	Therapeutic Result.	Months Elapsed since Operation.	Length (inches) of Ligaments Drawn out.
I	Anteversion, enlarged uterus, prolapse, with rectal symptoms	Good 1st intention	Good	Good	17	3½
II	Retroversion and retroflexion, without adhesion	Good 1st intention	Good	Good	8	3½ and 4
III	Prolapse, areolar hyperplasia of uterus	Good 1st intention	Good	Good	7	4
IV	Procidentia, rectocele and cystocele, hyperplasia of uterus	Good 1st intention	Failure (good for 5 mos.)	Failure (good for 5 mos.)	6	7
V	Retroflexion, prolapse, and enlargement of ovaries, parametritic adhesions	Good	Good	Good	6	3½
VI	Procidentia, rectocele, cystocele.	Good. Suppuration both incisions	Good	Good	2	3½ and 4

The tabulation of these cases show that the two in which were backward, and the one of forward displacements, accompanied by various complications, adhesions, prolapsed ovaries, etc., have been cured by this operation. The one of prolapse of the uterus, unaccompanied by cystocele and rectocele, has also been cured.

The one of complete prolapse, with large cystocele and rectocele, although for a considerable time apparently cured, has proven since to be a failure. In this patient seven inches of the ligaments were drawn out on each side, and this suggests the explanation that possibly there may be an abnormal tendency for the ligaments to be elongated.

The one of complete prolapse, with rectocele and cystocele, that has had but two months of convalescence, is entitled to a very guarded prognosis as to cure, and I have advised operating upon these latter complications.

From my own experience, I think it may safely be said there is no difference in the size of the ligaments dependent upon age or child-bearing. There is often a considerable variation between the ligaments of opposite sides. I have preferred to use the redundant portion of the ligaments to plug the external ring, instead of removing it, for two reasons: to lessen any possible danger of hernia, and to ensure that the patient's condition shall be no worse than before, in case the ligament should break away from its fastenings. There is but little danger of its sloughing if care be used in handling it.

The operation is not one of so great difficulty as has been claimed. Care in determining the landmarks, and delicacy of touch, rather than of sight, are its particular requisites. Of its dangers, the first is pyæmia, which appears as the one cause of mortality, and naturally suggests the question of sepsis; the other is of hernia in the wounds, which, I think, the method of closing the ring by the superfluous ligament will

decidedly lessen. So far, I have escaped both accidents.

As yet, I have subjected no patient to this operation until I have made a thorough trial of non-surgical measures for her relief and failed, but I feel sure that in certain cases in the future I shall operate much sooner.

Backward displacements of the uterus *which can be replaced*, even if complicated by adhesions or displaced ovaries, can by this means be cured, and our hospital clinics relieved of the large number of women whose treatment by pessaries is unsatisfactory both to themselves and us. It will be less often the operation is demanded by those who have time and money for other forms of treatment; but even among these will be found an occasional case where a prolapsed ovary or elastic adhesions interfere with the proper adjustment of a support.

I am not at all hopeful that in this operation will be found the cure for procidentia when there is a cystocele or rectocele of any considerable size, unless it be supplemented by the usual operations for these lesions. This conclusion is disappointing, and I trust future operations may prove it wrong.

Clinical Memorandum.

THREE CASES OF "HEREDITARY" LOCOMOTOR ATAXIA (FRIEDREICH'S DISEASE).¹

BY GEORGE B. SHATTUCK, M.D.,
Instructor in Clinical Medicine, Harvard Medical School, and in the Boston Polytechnic.

I HAVE only had time to write out these cases in the briefest possible manner. I regret it the less that the discussion of the previous paper has been rather long. I have not gone into the question of differential diagnosis or of pathology. This I regret the less because a paper was read upon the same subject by Dr. W. Everett Smith,² some two years ago. So it is not necessary to go over the same ground so soon before the Society again. Dr. Smith is here to-night, and he has sections of the cord which were made from one of his cases.

I had hoped that I would be able to show them to the Society, for specimens of the cord from these cases are very rare, as the autopsies have been very few; but unfortunately there is no microscope in the building, and I would take this opportunity, although not quite in order, to express the hope that some gentleman who has finished with his microscope, whether he is moribund or has ceased to take an interest in the subject, would give his microscope to the Library Association, rather than give it any more old books. I think it would be a very useful variation. The case reported which came under my own observation, exhibits most of the characteristic symptoms as they generally appear.

In regard to the frequency of these cases, in 1884 some forty cases had been tabulated. When Dr. Smith read his paper, he tabulated all the cases that were found up to that time. There were fifty-four tabulated cases, and subsequently, before he published the paper, he had heard of eight other cases, and he has heard of five since. This would make sixty-seven in

¹ Read before the Clinical Section of the Suffolk District Medical Society, January 11, 1888.

² Journal, Volume CXIII, p. 361.

all. Dr. Smith has just told me that Dr. Griffith, of Philadelphia, is preparing a report upon this disease for the Philadelphia College of Physicians, and that he has collected about one hundred and twenty cases. All this simply shows that the cases are rare, and although literature and practice have been searched very carefully for them, the number is still quite limited.

H. O., a boy fourteen years of age, born in New York, but living in a country town in Massachusetts, where he went to school, was brought to Boston for medical advice, the end of November, 1887, and his friends brought him to the City Hospital, where he came under my care. His own account of his previous history was that he had some illness when four years of age, of the nature of which he was ignorant, but he recovered, and was subsequently perfectly well. Six years ago, when eight years old, he noticed that he stumbled when he walked, and since then has walked less and less well in successive years, and now the difficulty in walking troubles him more than anything else.

He said that his appetite was good, the bowels somewhat constipated; otherwise the digestion was good, the sleep was good, there were no pains at any time, the eyesight was good, there was no trouble with the sphincters of bladder or rectum.

The temperature, pulse, and respiration were normal, as was the urine. Examination showed a well-developed, well-nourished boy of much more than the average intelligence; the tongue clean, protruding straight, with a slight tremor; the pupils were normal, reacting both to light and accommodation; there was no nystagmus; the left side of the chest was prominent in front, on account of a lateral curvature of the spine in the lower dorsal and upper lumbar region.

There was a soft systolic murmur, loudest at the base of the heart and to the left of the sternum; the cardiac area was normal. The lungs and abdomen were negative.

The gait was markedly ataxic; he could not turn quickly without falling; could not stand with his feet together, nor with his eyes shut. The motions of the hands were ataxic, he wrote with difficulty, and only when steadying the hand; he could not hold a glass of water in his hand, or carry it to his mouth. There were slight oscillations of the head, which were increased when he spoke; the speech was jerky and ataxic.

The grasps were strong: R. = 95, L. = 85, with the dynamometer. The knee-jerks were absent, the plantar reflexes present; sensation over the legs was slightly diminished, transmission was a little delayed; he could not distinguish a pin-point drawn across the leg from one drawn up and down.

The other members of the family are in a distant Western State, but the following facts were learned from a married sister, a very intelligent, healthy woman, with whom H. O. is now living: The first thing which attracted attention to H. O. was, at the age of eight years, a complaint of feeling tired and a certain unsteadiness in his gait; the trouble with his speech began more than two years ago, and was thought to have been worse than at present. The parents are about fifty years of age, are both strong, healthy, temperate people, and have had ten children in all. Of these children, two others—a brother,

the third born, and a sister, the youngest, and next to H. O. — are affected, as will be described, in a manner similar to H. O. The family history is an unusually good one: the grandfather on the father's side died of old age at ninety-seven years, the grandmother healthy until dying of a fever; the grandfather on the mother's side, a very healthy man, died of typhoid fever, the grandmother died at the age of eighty from an accident. The uncles and aunts on both father's and mother's side had all been healthy people; the mother expressly told this daughter, two years ago, that she had never heard of any nervous disease in any member of the family. Another brother, the third-born child of the parents, now twenty-four years old, was reported by my informant to have exhibited slight unsteadiness in his walk when seven years old, since which time he has grown gradually worse, and for the last eight years has lost the use of the lower limbs entirely. This brother is well developed and well nourished, has no affection of the speech, except that he cannot talk long at a time, on account of weakness, but has a bad curvature of the spine.

A little sister, the youngest child, now ten years old, first complained of weakness and a tired feeling at any exercise, with palpitation of the heart, when from five to six years old, at the same time an awkwardness in her walk became apparent; she also has a curvature of the spine. My informant reported her other brothers and sisters as unusually strong, healthy, well-developed people.

Taken in connection with a considerable proportion of the other cases hitherto reported, these cases tend to show that the term "hereditary" ataxia is a misnomer and misleading; the term Friedreich's ataxia — Friedreich first reporting and recognizing the disease — is open to the objection common to all such names; namely, it describes nothing. It is probable that the disease in these cases and in others, was of an older date than the first apparent symptoms; that it is, in fact — in contrast to true locomotor ataxia — a want of development, rather than a degeneration of the spinal cord.

Reports of Societies.

MASSACHUSETTS MEDICAL SOCIETY. SUFFOLK DISTRICT. SECTION FOR CLINICAL MEDICINE, PATHOLOGY AND HYGIENE.

ALBERT N. BLODGETT, M.D., SECRETARY.

STATED MEETING, Wednesday, January 11th, at 19 Boylston Place.

The SECRETARY read an invitation from Professor Putnam of the Peabody Museum of Ethnology and Archaeology at Cambridge, to the members of the Suffolk District Society to meet him at the Museum and inspect the relics there arranged. Dr. Blodgett said:—

Some time ago Dr. Putnam invited the Section to meet at Cambridge and inspect the relics which he had succeeded in recovering from the Serpent Mound, and other places of archaeological interest in the West, and which are preserved in the museum at Cambridge. The Section in its meeting for November ordered the Secretary to arrange for such a meeting of the Society at Cambridge. Professor Putnam was shortly after-

ward taken seriously ill, and was not able to receive the Society. He is now recovered, and can meet the Society either the last of this month or the first of next. The evening of January 25th I think is not occupied by any meeting of a medical character in this building. February 8th I think is the evening designated for the meeting of the Surgical Section. If the society wishes to designate an evening I should hope that it would take that matter into consideration. I know of nothing to interfere with the evening of the 25th, if the Society wishes to take that time. The entire Suffolk District Medical Society was invited to attend the meeting of the Section at the Museum. I hope that some action may be taken upon this communication.

DR. MORTON PRINCE moved that the invitation be accepted for the 25th. Carried.

DR. BLODGETT: I would like to add that Professor Putnam very kindly invited the society to meet at the Museum in the afternoon and inspect the collections there arranged, and then to listen to a lecture in explanation of them in the evening. That perhaps would hardly be practicable, but the invitation was sent to me, and I think it would be very desirable if it could be accepted in that form. I suppose, however, that it would be hardly practicable for the physicians of Boston to go in the afternoon, and consequently the evening hour seems to me personally more likely to prove favorable for most of the members of the Section.

By vote of the society the meeting was appointed for January 25th at 7.45 o'clock.

DR. W. N. BULLARD read a paper on

A CASE OF CEREBRAL LOCALIZATION WITH DOUBLE TREPHINING.¹

DR. J. J. PUTNAM said: We have all listened with great interest to this paper. Cases of brain operation are rare among us, and we should learn from them all that we possibly can. Of course every one looks with a great deal of anticipation and hope to the future of cerebral surgery, and at the same time the chances of marked success would seem to me to be moderately limited. Although as Dr. Bullard has said, we can, through our knowledge of certain portions of the brain, localize with considerable accuracy certain lesions, especially those involving the motor functions, it is, on the other hand, I think, very difficult to tell what the nature of the lesion is, and the exact relation of the disease to the symptoms.

The difficulty of determining at what depth a tumor lies, the fact that tumors which grow very slowly so often occur almost without symptoms, and our ignorance of many of the conditions that govern the occurrence of symptoms, would seem, I think, to make us very properly cautious in raising any very sanguine expectations about the result in most cases. And although the case before us is highly interesting, and justified Dr. Bullard's claim in regard to it, that the diagnosis as to the lesion was made during life, it cannot count as one where much benefit could have been hoped for.

In these congenital troubles, I don't see how we can expect to produce a result that would be particularly favorable unless we can operate upon them very early. And then the trouble comes in that the difficulties of early localization are greater than at a

later time. The rapidly developing brain of the child is so susceptible to permanent injury; its growth is likely to be retarded; and an atrophy involving not only the seat of the lesion, but that of the whole hemisphere of the brain is liable to follow from any injury received at birth or in the very early years of life. Moreover, the fact that localized lesions, even if they might have been removed soon after they occurred, give rise to secondary changes not only in the hemispheres of the brain but in the deeper lying tracts, would, it seems to me, render this class of cases not a favorable one for operations of this kind.

In regard to the operation itself, of course the points are many and interesting, and I would not attempt to touch upon them at any length. One remark made in connection with a case operated upon in New York struck me as significant. It is important that the opening in the skull should be large; that quite a window should be cut, instead of the ordinary trephine hole, the belief being that under those circumstances the brain is less liable to protrude from the opening, and that the wound is more likely to heal favorably.

I recently saw a specimen from a case in New York, which unfortunately terminated unfavorably, where, although no suppuration had taken place and no sign of septic poisoning showed in life, the patient died from what was considered as red softening, immediately beneath the seat of the operation without it being possible to discover any cause for it. The brain simply became softened; that was all one could say about it. It has usually been considered that serious results from operations are not likely to occur. Dr. Spitzka, in experiments on animals, has gone farther than that, and says that not only are unfavorable results not likely to occur, but a second operation in the same region is even less likely to do harm.

I cannot help saying a single word about a case which I saw myself, which seems at once an illustration of the difficulties in the way of the diagnosis of cerebral tumors, and also of the possibilities of cerebral surgery.

It was the case of a woman who exhibited through life no localizing signs except toward the end of her life a slight facial paralysis on one side. Beyond that she had an intense headache, and a progressive stupor. She died, and at the autopsy a large sarcomatous tumor was found pressing apart the sides of the fissure of Sylvius, having caused no real injury beyond the pressure, to the brain itself, and being attached to the dura mater on the sphenoid bone with very slight attachments. If the tumor could have been reached it certainly could have been removed without injury, I think. On the other hand it had grown to the size of one-half or two-thirds of one's fist, without its being possible to diagnose it as central or cortical.

DR. MORTON PRINCE said: I think that this is a most interesting case, and that the reader is entitled to credit for his successful localization of the lesion. In regard to the possibilities of the operation, I feel like being a little cautious; feel as if we must and go ahead too fast. We don't yet quite know what the possibilities of brain surgery are.

But whatever the future may bring forth, there are certain fixed principles upon which, in the light of our present knowledge, brain surgery must be based. These are that an operation should be undertaken only for the removal of a lesion causing symptoms of

¹ See page 162 of the Journal.

irritation, or threatening the life of the patient. All operations thus far have been based upon this principle. A brief survey of these cases will make this clear. Up to this time there have been reported only fifteen cases of pure brain surgery. Of these, eight were cases of tumor, of which only three survived the operation, and of these three one died later from recurrence of the tumor. In the remaining seven cases, the operation was undertaken for the removal of a supposed lesion causing epileptic fits; in these seven cases there was recovery from the operation itself. It is interesting to note that the operator in these latter cases as well as in the successful cases of tumor was Victor Horsley, who is the only operator, I believe, in whose hands the operation has not ended fatally. He has operated nine times with only two deaths. In one of his cases only was death the immediate result of the operation, and in this case it should be said that the patient was in a very critical condition when the operation was undertaken. The second death (the one just referred to) was due to recurrence of the tumor. In the seven cases operated upon for epilepsy due to irritative lesion, there was complete and permanent cessation of the fits in four cases, and more or less improvement in three. In this latter class of cases the operation was undertaken with the idea as of removing the diseased tissue which was regarded the point of irritation and the exciting cause of the fits. Now it will be seen that the principle underlying all these operations was that there was a lesion of the brain, causing not merely paralysis and loss of function, but aggravating irritative symptoms, or else threatening life. In one case the fits aggregated three thousand in two weeks. To operate upon the brain in such cases as these I believe to be sound surgery and sound neurology, and there seems to be a legitimate, even if limited field in this direction, and perhaps a brilliant future. Time, however, can only settle this. But when we go from this to cases of paralysis, and that too with spastic symptoms, I confess I feel very doubtful. I am unable to see on what sound principle of neurology, operation in such cases can be based. I am unable to understand how a pure paralysis due to a hole in the brain is going to be improved by making the hole bigger. All that we could do by operation would be to cut out more brain, and that is equivalent to enlarging the lesion, and would simply increase the extent of paralysis. Furthermore, when spastic symptoms of long standing exist, as in the case reported, there undoubtedly exists secondary degeneration extending down along the direct fibres through the motor tract to the cord, and it is to this secondary degeneration that the spastic condition is due. Mere removal of the cortex could not then in any way relieve these symptoms.

There is one point of which the reader spoke and which I think should be emphasized still more, and that is the necessity, if you are going to operate, of taking into account only the symptoms themselves in localizing the lesion. That is, the proper localization depends entirely upon the grouping of symptoms, and it is only by such grouping that we can localize the disease. It makes no difference where the original injury to the skull is situated, and this should not be considered. This seems a trite remark, and yet I think it not uncalled for. I remember seeing a case the other day, a case of aphasia, where the trephining was done on the top of the head, attention being di-

rected to that spot on account of a former accident. Of course the lesion must have been lower down.

Perhaps there is another class of cases where there is a possible field for this operation, and that is where, in cases of this kind, there is not only paralysis of one or more members; but where there is also athetosis or clonic localized spasms of severe type. I saw a case of this kind some time ago. I suggested the operation, but did not see the patient again.

I think perhaps in that case something might have been done. I do not say this to criticise the paper, for I think the reader should be highly gratified at his success in localization in this case.

DR. J. COLLINS WARREN: I have very little to say, but have studied this matter up a little. I was struck by what was said about the caution with which we should go ahead in this region of surgery. I think that corresponds pretty well with the writers on this subject, especially in works on surgery. They say that the study of the cerebral topography, and the physiological action of these centres indicates rather what not to do than what to do. That is to say, the opportunities for interfering and trephining are comparatively few as compared with the indications when we should abstain, and yet many of these indications might tempt one, ignorant of cerebral topography, to interfere and relieve pressure or something else there.

For instance, if we have injury with symptoms of paralysis, which correspond to that tract, not too extensive, that might perhaps be a reason for interfering. If, for instance, after a blow, we have paralysis of the arm and leg, that might be an indication for trephining at the upper portion of the fissure of Rolando. But if we have total anaesthesia, not only is the motor tract involved, but an indefinite amount of brain convolution behind the ascending parietal. That is, it is an unknown quantity, a considerable surface, so that in order to reach that surface we would have to put on four or five trephines side by side, in order to uncover it and relieve it. There it would be contraindicated. Limited paralyses or anaesthesias, with well-defined injuries, give the indications for interference in a surgical case.

From the surgeon's point of view, there is one other indication for interference, and that is in hemorrhages from fracture. In a diagram in which the middle meningeal artery is represented, we can see how, by measuring back from the external angular process three-and-one-half centimetres, we can strike the exact point crossing the middle meningeal artery, and if we were to have symptoms of pressure in that part of the brain substance, for instance, of facial paralysis, we could readily interfere, and trephine at that point, and get at the artery comparatively near its origin. If we found that there was any difficulty at that point, but it appeared that there had been a hemorrhage from the artery, the indications are to put the trephine on the same horizontal line but more posteriorly, because the blood-clot may be in the posterior part of the brain rather than the anterior, in some cases. The reported cases are, I think, a considerable number, although I cannot quote them.

Dr. Prince spoke as if trephining for epilepsy were comparatively a novelty. I think that it is an operation that has been done considerably, although perhaps done in a different way, such as trephining for simple and depressed fractures. I would like to ask

if there is any special localization, other than the determination of the seat of the depressed fracture.

Dr. PRINCE: I referred to a different form of operation. Not merely trephining, but removing a portion of the brain, even when there is no reason to suppose that there is a gross lesion.

Hughlings-Jackson has suggested that in cases of epilepsy and epileptiform convulsions, where you are able to trace the beginning of the convulsion to a focal point in the cortex, it would be justifiable to remove that centre as the focus of the epileptic discharge. For example, suppose the convulsion always to begin in the thumb, and to progress in a definite order throughout the body, in that case the centre for the thumb will be found to be the seat of the most intense discharge, and he considers it good neurology and surgery to remove this centre. Acting upon that advice, Dr. Horsley, in one of his cases did did remove the centre for the thumb, with the result that he cured the fits. It is in that sense that I speak of brain surgery as being a novelty, and it is in this field that perhaps there is a considerable opening for the future.

Dr. S. H. WEEKS, of Portland, a guest, was introduced by the chairman, and said: I am indebted to Dr. Walton for this pleasant opportunity of meeting the gentlemen of this Society. I would much prefer to listen to the discussion than to have anything to say, and yet I am sure you will allow me to express my pleasure and great satisfaction to find such a number of men, who, while they are doing general work, yet are devoting much of their time to special subjects such as this of brain surgery. My work is that of a general surgeon, and yet I am specially interested in everything which pertains to local surgery, because it is to the work of the specialists, men who are doing the special work, that the general surgeon, by and by, and through him the community at large, are to receive the greatest possible benefit; because when you have explored and investigated this field, and have rendered the operations which are now hardly to be thought of, legitimate and practical, then the general surgeon will be able to come in and do the good which he cannot do without your special work.

If I may judge from my own experience and observation, the operation of trephining the skull is not attended with as much danger as is supposed. I recall a case (and I wish I could detail it more accurately than I am able to), that I operated upon at the Maine General Hospital some year or eighteen months ago, in a young man who was having epileptic fits every week, and sometimes twice a week, following an injury which he received when a lad, some fourteen or fifteen years ago. He was riding a horse for raking hay, and was suddenly thrown from the horse, and as the rake revolved one of the teeth, made of steel, struck his head near the bregma and I think a little to the right of the median line. At the time there was a compound comminuted fracture with depression. The physicians at the time removed some portions of the skull.

The wound healed, leaving a cicatrix, and in the course of a year or two there commenced convulsions, first in one hand, and I am sorry that I am not able to say which, but I hope some time to report the case in the JOURNAL, that you may have the exact measurements and symptoms, and derive more advantage than from any recital here now. I am sure that the convul-

sions first started in the hand, and then extended into the arm, and then involved the entire side. He had been at the hospital once before, and after consultation we refused to operate.

He went home and suffered another year, and his convulsions becoming very frequent, he again returned, and said: "If there is anything that you can do, I want it done, no matter what the risks or dangers are." At the second consultation we decided to operate. I repeat this more to show the safety of the operation than anything else. Making an incision through the skin, I found that there was a portion of the skull that had not been restored, and here the scalp and dura mater were adherent. I dissected off the scalp from the dura mater, directing my dissection as well as I could so as not to open into the cavity of the arachnoid, and came to the edge of the bone, which seemed to be indented, and then took out a section of bone. Not finding a depression there, I felt that I had not reached the difficulty, and took out another portion, and upon that button there was an exostosis from the inner surface to the extent of three or four lines, extending down on to the dura mater and firmly adherent to it. After I had loosened the segment of bone, finding this projection adherent, I was obliged to take out an elliptical portion of the dura mater in order to remove the bone. I brought the edges of the dura mater together with small catgut suture, and then closed the external wound, applied a simple dressing, and put the patient to bed.

There were almost no unpleasant symptoms following. In fact, so comfortable was he after the operation, that he would sit up in bed in spite of my cautions, and declared that the only thing that he was kept in the hospital for was to let his hair grow again. I believe the danger in trephining is not as great as we have supposed. And while there are many diseases that we may not be able to cure by brain surgery, yet I believe there are many cases which are capable of cure, or of being benefited by these operations. One word in reference to the future of this patient. While the fits were not cured, they were very much mitigated. I saw him a few weeks ago and inquired particularly for the symptoms, and he said that once a month or so he would have a slight convulsion, but nothing to compare with what they were before; and were it not for his intemperate habits, which he continues, I believe the benefit would be much greater. There are other cases that I think of, but I will not relate them. I thank you for your courtesy and kindness, and shall be very much interested in listening to the further discussion.

Dr. P. C. KNAPP said: I have been very much interested in the paper as showing the very exact localization of the lesion. I would agree with Dr. Putnam and Dr. Prince in what they have said. There is one point, however, that seems worthy of notice, and that is the fact that although there was apparently a lesion in the cortex, which is so common in these cases, there were no convulsions at any time in the history. A year and a half ago, Dr. Sachs, of New York, laid special stress upon the presence or absence of convulsions as an important symptom in the localization of the lesion. In cases of intra-cerebral hemorrhage or embolism, he believed that there were no convulsions, but in cases where there was cortical disease, he believed that convulsions were present.

This case, I think, is of special interest, as showing

the presence of probable cortical disease and entire absence of convulsions. I would say, moreover, that as the case was reported, I do not see what justification there was for either operation. Certainly, the cicatrix on the right side caused no symptoms, and after so long a duration there was no evidence of any disease there to be operated upon. Nor do I see what could have been gained in any way by operating upon the other side, for the symptoms were those merely of paralysis and secondary degeneration, and no operation whatever could have helped the patient.

I agree with Dr. Prince fully that in case of convulsions or athetosis, perhaps there might be benefit in removing portions of the brain substance, but certainly there is one point that might have a bearing in such cases. In some cases that I have seen, where the limb was only partially paralyzed, there were athetosis or convulsions starting in the hand. Here, if you were to cut out the centre for the hand, which was the chief seat of the lesion, you would produce absolute paralysis of the hand: this would deprive the child of a fairly useful hand, and would leave him in a less advantageous position for getting through the world than he was in before.

DR. PUTNAM: Of course, in localization we refer chiefly to cortical localization. It seems to me, however, that this case is one where localization of that kind is really not possible. What we had present was a hemiplegia, apart from the secondary changes. The aphasia, I take it, would count for little or nothing, for the child had never spoken. Even if that were not so, the function of speech would be probably sooner lost in a child's brain than in an adult's, so I cannot see how we could strictly localize the lesion. It was evident that it involved structures either so extensive or so far beneath the surface as to include all the tracts coming from the opposite side of the body; that is to say, it must have been a very extensive cortical lesion, and in that case not strictly localizable, or else a moderately deep-seated injury; and I don't see how it would be possible to localize it with certainty in one part rather than another of the motor tract, except that we might, perhaps, say that it was not in the pons.

DR. KNAPP: I would like to ask Dr. Prince one question. In speaking of Mr. Horsley's removing portions of the cerebral cortex where the convulsions always began in one portion of the body, he said that Hughlings Jackson advised it. I would like to know whether he recalls any case in which Mr. Horsley operated where there was no gross lesion of the brain. It seems to me that in every case he found some thickening of the meninges or a tumor, or something of the sort. I don't recall any case where there was no disease whatever, where there was simply the functional disease starting at that point.

DR. PRINCE: There were, I think, two cases. In one he removed not only the tumor, but also the thumb-centre. In this case, he diagnosed a doubtful lesion. He knew that there was a lesion, but was in doubt as to its exact nature.

As I understood the report, when he came to open the skull he found no lesion whatsoever, but he still removed the portion of the brain corresponding to the seat of the epilepsy. At any rate, Jackson advised it, and said that he would advise the operation in the future. It seems to me that this is a sound principle to go upon simply as a theory in a very grave case. Of

course, you would not operate upon a case of that kind unless it were a case that justified some risk.

DR. KNAPP: I didn't know that a case had been reported where there was no gross lesion.

DR. WEEKS: In speaking of the localization of the different functions of the brain, I recall a case that came under my observation several years ago, where a man who had organic disease of the heart was taken suddenly with aphasia, and the sickness lasted only two or three weeks. His sickness increased day by day, manifesting decidedly cerebral symptoms. The most prominent symptom was the loss of the power of speech. It was at the time when the discussion as to the seat of language was going on in the medical journals and societies, and when the medical opinion was not as well satisfied as now in regard to the localization, and yet my attention had been called to the anterior portion of the left hemisphere, the temporal lobe, as the seat of language, and I watched the case with a good deal of interest. When he died, I was successful enough to get an autopsy, and, on taking off the calvarium, I found the dura mater at that point a good deal congested; and on opening through the membrane, and going through a very thin portion of the cortical substance of the brain, I came to a large abscess.

Now I believe that to-day, if you had such a case as that, you would operate upon the abscess and give exit to the pus, and in such a case as that I believe you would save the life of the patient. Here was the seat of the lesion, and, so far as any case can prove the theory, certainly this goes to substantiate the theory of the localization of the seat of language.

DR. WALTON: I have been very much interested in hearing the report of the first case, so far as I know, that has been done in Boston of this sort. I am quite agreed as to the importance of the surgeon's being prepared for early operative interference in just the cases that are indicated. I do not think, however, that this variety of cerebral surgery, where the healthy skull is trephined without fracture or other injury, has so great a future as, perhaps, was hoped for it at first; certainly no such future as abdominal surgery, for the cases are really limited in which the operation is sufficiently indicated.

I agree with Dr. Prince that, as we eliminate the cases, we shall finally become pretty well sifted down to lesions which are irritant, and lesions that bring about decided pressure symptoms, in which we feel pretty certain that we can relieve pressure. I think there are certain localized abscesses which can be operated upon with advantage.

All these lesions must be decidedly near, or at the cortex, or we are not justified in operating.

The result will be, as it seems to me, that there will be so few cases in which we will feel ourselves justified in operating, that opportunities will be rather rare. We have been on the lookout at the Massachusetts General Hospital for an acceptable case, and I fancy it has been true at the other hospitals, and there has not been, so far as I know, any case admitted. The nearest we have come to it was one case in which we did diagnosticate a tumor in the cortex. There was paralysis or partial paralysis, and if I remember rightly, convulsions of one arm, in which we were sure that the tumor was at the cortex, and advised operation, but the patient demurred.

I was interested to hear Dr. Putnam speak of a

considerable opening in the skull. I think it is important to make as large an opening as possible, not only for the sake of after-results, as far as the case is surgically concerned, but also for the sake of helping us to localize. My attention was particularly brought to that point by going to the demonstration of Drs. Warren and Richardson, last evening, in which the skull was trephined on the cadaver and the fissure of Rolando found. The fissure was localized according to the regular method, the opening made perhaps three-quarters of an inch in diameter, and directly in the middle of the opening was a fissure, but it seemed to me at almost right angles with the direction one would suppose it to go. But on removing the calvarium and dura mater, it was afterwards discovered that it was the fissure of Rolando, but it had taken a turn at that point.

It is not always so easy, even after the brain is removed, to determine just where the various fissures are, as sometimes those fissures which should be the most distinctly marked are the least so, and other less important fissures become more marked. And in this case I should say that the frontal fissure was much more marked than the fissure of Rolando.

DR. BRADFORD: I did not have the pleasure of hearing Dr. Bullard's paper, but he has allowed me to read it, and I think it covers the ground pretty thoroughly. It only remains for me to say what the reasons were for performing the operation. I think some apology should be made for an attempt at an operation in a child who was idiotic. The operation was done in this case chiefly for the reason that it was hoped that the spastic symptoms might be relieved. The parents were told distinctly, that it was purely experimental surgery, and they wanted to have the operation done, even on those grounds. Notwithstanding that in these cases of spastic paralysis the cortical substance is in a large number of cases involved, it was hoped that possibly some irritative centre might be found, and the removal of that might relieve the spastic paralysis of the leg and arm, and render the locomotion of the child better. The result proved that the operative interference was not justified except as an experiment.

The cause of death in this case is, I think, somewhat interesting. The child died unquestionably of shock, and the question arises whether the double trephining may not have been more than was proper to have done.

It is a question whether it might not have been better to have trephined in one locality, and waited before trephining in the other. It did not seem so at the time, and the double trephining was undertaken; trephining over the cicatrix to satisfy the parents, who believed that the condition was in some way due to the depression of bone. Both Dr. Bullard and I thought not. That double trephining may have given rise to the shock.

Another cause of death may have been the use of morphia before the operation. The child was given morphia subcutaneously or by the mouth a short time before the operation, carrying out Mr. Horsley's idea for the purpose of contracting the vessels in the brain. I think a larger dose was given than would have been needed. One-twelfth of a grain was given and I think one-twentieth would have been better. At any rate, during the etherization the child was more or less under the influence of the narcotic. That may have

acted injuriously, although the child came out from the ether and morphia before dying.

Another cause which may have given rise to death, was bleeding from one of the larger vessels in the diploe, during the operation. That was plugged by a piece of wood, but the child lost some blood. I think, so far as we can judge from the single case, it would not be desirable to do a double trephining in a child.

DR. M. H. RICHARDSON said: I was unable to hear the paper, for which I am very sorry, but I have a word to say in regard to the outlook for operations upon the brain in instances of this kind. It seems to me, as Dr. Walton has said, that the probable future of cerebral surgery does not promise the results which we get in other parts of the body, the peritoneal cavity for instance.

My own experience in trephining for the sake of finding an abscess, for removing a possible irritating cause of epilepsy, has been uniformly unsuccessful. I reported two cases a year ago of trephining for epilepsy, and another for cerebral symptoms after compound fracture, without any benefit whatever. And since then I have trephined to evacuate a probable abscess after gun-shot wound, a good case for symptoms arising after injury. In the latter case death followed, and in the first two cases there was no benefit whatever.

It seems to me in a certain number of cases, where symptoms of definite localized irritation can be made out, at present it is the duty of the surgeon to interfere on the chance of doing some good. But it seems to me that as matters now stand, the chances are that in a large number of cases there will be no permanent benefit following the operation.

DR. BULLARD: I would like to say one or two words in regard to cerebral surgery. I agree entirely with Dr. Prince and Dr. Putnam in regard to the fact that we should not be too fast in brain surgery. I think that nobody who has had anything to do with the localization of lesions, fails to understand the difficulties, and the many problems we have to consider and the very small number of cases in which we are justified in operating.

But it does seem to me that such a class of cases exists, and although the most prominent cases are those where convulsions or irritant symptoms follow, yet we must not limit ourselves to them entirely. Ross says that the larger number of hemiplegic cases and convulsions come on at least by the time the child has reached eight years, or sometimes a little later. I have not experience enough to know whether that is true, but it is certainly true that, in a certain number of cases of spastic hemiplegia, the convulsions do come on later. Now I should be very slow to advocate operation in cases of spastic hemiplegia unless there were some special reason for doing so beyond the mere fact of the existence of a hemiplegia; but I believe that there may be certain cases where it would be advisable to perform the operation.

In this particular case I think we had good ground for localizing the lesion as we did. Of course I have not gone into all the details. A good many symptoms were absent which would have been likely to be present if the lesion had been in other parts of the brain. Of course, in such a case, the operation is done with the understanding that it can only be experimental.

DR. BRADFORD: The sense of the meeting seems

to be in disparagement of cerebral surgery. I don't think we shall put ourselves in the line of modern surgery if we take the ground that cerebral surgery has not a future, and I think we can anticipate a brilliant future for it. We are only in the beginning and, I think, what has been done shows that there is a great deal more to gain when our experience is greater. I think it is in the recollection of most of us here, that here in Boston the statement was made on the best surgical authority, that ovariectomy was not a justifiable operation. We have lived to see that dictum not accepted, and I think we will find that cerebral surgery has a future before it that we have not yet thought of.

DR. GEORGE B. SHATTUCK then reported some cases of

FAMILY ATAXIA.²

DR. P. C. KNAPP: I have listened with a great deal of interest to Dr. Shattuck's report, and I am indebted to him for the privilege of examining the boy when he was at the hospital. As Dr. Shattuck has said, these cases are so extremely rare that every additional case is of utmost interest. The ordinary term for the disease seems to me to be a misnomer, confusing it with true locomotor ataxia, with which it really has nothing to do.

Dr. Shattuck's case did not present one of the very common symptoms seen in Friedreich's disease; namely, nystagmus. It did, however, present other symptoms which are characteristic of the disease, and which are rarely, if ever, seen in *tabes dorsalis*; namely, the curvature of the spine and the disturbance of speech. Furthermore, in the cases of Friedreich's disease which have been reported, one of the very striking features is the absence of the most constant symptoms of *tabes dorsalis*, such as the lancinating pains, the disturbances of sensibility, and all the disturbances of the pupils. There is a very early onset of the ataxia, which, in *tabes*, is a symptom which marks the second stage, and may not come on for fifteen or twenty or twenty-five years after the first symptoms of the disease. Furthermore, in Friedreich's disease we rarely, if ever, get the less common symptoms of true *tabes*, such as the various crises, and joint diseases.

I think the cases reported by Dr. Smith were in a way rather exceptional, for most of them had some gastric disturbance about the onset of the disease, yet it was nothing at all like a true gastric crisis. The disease is, as Dr. Smith's autopsies show, a combined sclerosis of the cord, rather than any especial disturbance of the posterior columns.

I have brought with me to-night, thinking it might be interesting, a book on the nervous system, which gives a section from Dr. Smith's case, and also a series of sections of the cord in one of Friedreich's original cases; and from some of the sections it will be seen that the degeneration is not only a very complete degeneration of the posterior cornua, but also extends into the lateral pyramidal tracts, the direct cerebellar tracts, and passes around the cord, involving, also, the anterior pyramidal tract, the columns of Törck.

The cases in the family of Dr. Shattuck's patient are also interesting, as beginning quite early. Many of those reported have been found to come on about the time of puberty. It further is distinguished from

true *tabes* in that the latter never comes on, so far as I know, in childhood, and, in the vast majority of cases, is connected with a previous syphilitic taint, which has not been found in the cases of Friedreich's disease. Another symptom which was very well marked in this case is one which is stated by both Erb and Spitzka to be absent in Friedreich's disease; namely, the swaying of the body when the eyes were shut, and the feet placed together. In this case the swaying came on without the closing of the eyes, no matter where the feet were. The patient could not stand when he shut his eyes, unless we propped him up in a corner.

As I said, the disease is rather a general degeneration of the various fibres in the spinal cord, due very likely in some cases to some defect in the cord itself — possibly, as has been noted in one or two cases, to an exceedingly small cord. The disease is of great interest, especially among what might be called the developmental diseases of the nervous system. I think we are all indebted to Dr. Shattuck for presenting the case before us to-night.

DR. W. E. SMITH said: I think Dr. Shattuck's case is a typical one as regards the symptoms, and far more typical than some of the cases that have been put on record as falling under this disease. In regard to the nomenclature, I quite agree with Dr. Knapp in his remarks that it is not a true locomotor ataxia, and perhaps I would put it stronger than he has, and say that it is not a locomotor ataxia at all. At the time that I read my paper, Dr. Hammond felt a little slighted that his cases, which were reported in 1882, were not incited. But my reasons for not mentioning them I stated at the time to him, and it seems to me that they were sufficient. He reported six cases that had come under his observation, but in none of the cases had any symptoms of ataxia occurred, as he takes particular pains to say in regard to each of them. "There was no ataxia present." As I said, why call the disease ataxia?

There were some cases reported by Dr. Coleman, who lived in Arkansas, but they had marked pulmonary symptoms, and one of them vomited large amounts of pus. I did not include Dr. Warren's cases, for the reason that they had not been put on record in print. I think that considerable confusion may have crept into the discussion of the disease from its supposed connection with locomotor ataxia.

In regard to the reported number of cases, I think I found about sixty, but Dr. Griffith, of Philadelphia, is preparing a paper upon the subject, and writes that he has collected something like one hundred and twenty cases. From what sources he gains his cases I am unable to say, but I more than suspect that it is from records of cases that have not been published.

In regard to the causation of the disease, I have very little more to say than I said in the paper; namely, that habits of drunkenness seem to play an important part. Masturbation has been supposed to be an element, and I inquired into it in my cases, but I am quite convinced that it did not exist. Of the subsequent history of my cases I have very little to add. The four whom I then said were surviving are still alive.

The girl whom I pictured is mentally less acute, although she was then a simple existence. She did take a little interest in hearing the town topics, but now takes none at all, I am told. The father of the family, whom I took to be an exceptional case, in that

² See page 168 of the Journal.

the disease developed at the age of sixty-six, has had several attacks similar to the one I described, leaving him in a pretty helpless condition so far as any active work is concerned. Two of the younger girls are still living, and in practically the same condition. The disease does not seem to partake of any paralysis, as Dr. Hammond's cases would seem to indicate, but is purely ataxic. In these cases, the girls, when asked to move the limbs, felt the power to do it, but were surprised that they did not move. When they did move them they went by jerks, and not in any coordinated or orderly way.

DR. PUTNAM: I have been very much interested in the disease ever since I saw two cases at the hospital that Dr. Smith afterward reported, and had an opportunity of examining the specimens, and also two other cases at the Massachusetts General Hospital, which were at the Out-Patient Department, and afterwards in the Wards, under the care of Dr. Ellis.

These cases belong, pathologically, among the so-called "combined sclerosis" of the spinal cord, and as such are perhaps related clinically, in some degree, with the other members of the same group, — spastic paraplegia and ataxic paraplegia.

In many of these cases there are changes in the ganglion cells besides the fascicular degeneration, and the whole process is sometimes associated with extensive degenerative changes elsewhere in the nervous system.

DR. SHATTUCK: With reference to the name it seems to me that it might well be improved upon. I don't like "Friedreich's disease" as a name, because I think it is a bad thing to call any disease by a man's name. A name ought to be in itself a description to a certain extent of that which it names. The word "hereditary" is certainly out of place, and "locomotor ataxia" is so much associated with the disease which we previously knew as such, that it also seems undesirable to apply it in this case. Something better certainly could be easily arranged.

With reference to one or two points that Dr. Knapp has spoken of: The nystagmus, I do not consider so constant a symptom as he seems to consider it. My impression is that one-third, and perhaps one-half do not show it. In regard to standing with the eyes shut (Romberg's Symptom), certainly Friedreich described it in connection with his earlier cases, and regarded it as one of the symptoms to be looked for.

DR. PUTNAM: I merely would suggest in regard to the matter of name that there may be the same objection to the title "family ataxia," for if the case that I reported two and a half years ago was really such a case it tends to upset that fact, for there has not yet appeared another case in the same family. Of course they might develop yet.

DR. SHATTUCK: The question of development at puberty also, is an important one. That was Friedreich's impression when he first described the disease. But I think now in the cases as we have them tabulated that we find quite a large proportion develop without reference to that period, and develop at a much earlier age than the age of puberty.

DR. SMITH: In regard to this latter point in the case which I reported, the mother was very sure that the earliest symptoms occurred at the age of puberty, and I labored for some months under that idea, but on further questioning her I found she had associated the change in their gait with changes in the other

functions of the body, and that really the first symptoms appeared between the ages of five and seven, and I confirmed the statement of the mother by the statements of the boys and girls who grew up with the patients.

DR. SHATTUCK: I believe, as Dr. Smith says, that a still larger number could be found developing at a very early period if we could get the true facts. It seems to me that increased acquaintance tends to prove that this disease has a different pathology from the ordinary locomotor ataxia, from this point of view; that it is a disease from want of development of the nervous system, while in the other we have a disease of degeneration. In many of these cases the nervous system has, I imagine, been from the very beginning very defective.

AMYLEN-HYDRAT.

DR. FRANCIS H. WILLIAMS then exhibited the new drug, amylene-hydrat. He said: This substance may be used as a substitute for chloral. It has a peculiar odor something like ether, and the taste is camphor-like, with an after-taste of peppermint. It is a clear, limpid liquid, and is fairly soluble in water. It takes about eight parts of water to dissolve one of the drug, and it is quite freely soluble in alcohol. The dose is from half a drachm to a drachm, 3 to 5 c.c. It does not act so strongly as chloral, it is not so powerful a drug, but on the other hand it is free from some of the dangers of chloral. It does not act to depress the heart and respiratory centre as much as chloral does, and for that reason is a safer drug to use.

In many cases it seems to work well, in a smaller number it has not been very efficacious. In one case for example, in Dr. Mason's service, forty minims of the drug were used in a uterine case where the patient had slept very poorly for several nights. She had some pain. One-sixth of a grain of morphia, repeated, was not able to give her the required sleep. This new remedy was given at 10 o'clock. At 10.15 she was asleep, and she slept nearly all night. As a rule the after-effects are not unpleasant. Here and there a few inconveniences are experienced from it. In one or two cases the remark was made that the patient experienced a pleasant sensation for an hour as though drunk, and was somewhat silly. In this case she felt contented, and went to sleep in about an hour.

I will not do more than call your attention to the drug and suggest that for certain cases it is likely to be a valuable substitute for chloral, but a better reason for not saying more about it is that perhaps Dr. Mason will be kind enough to tell us something of his experience in using the drug. I have reports of cases where it has been used in Germany, and in about eighty per cent. of the cases it has proved satisfactory. Unpleasant after-effects have not been noticeable.

DR. A. L. MASON said: I have a brief memorandum of some of the cases, but I will not delay you with it at present except to say that they were all cases of marked insomnia. There were two cases of rheumatic fever, with heart complications, in which we obtained four hours' sleep. In one case of severe measles four nights of uninterrupted sleep were obtained. One restless typhoid patient was not quieted by urethan, chloral, bromides or opium. Drachm doses of amylene-hydrat gave a good night's sleep. A case of acute tonsillitis, sleepless for four nights, and

another patient with dyspnoea, slept well after half a drachm. A case of abortion obtained good sleep for five nights.

Another patient in whom urethral caruncles were removed, who had sleepless nights, and a uterine case, in which one-sixth of a grain of morphia repeated was of no avail, had a good night's sleep after forty minims. And the same dose answered the purpose in a case of chronic nephritis with insomnia. A patient with cardiac insomnia, who has been treated with everything else, has had from five to seven hours sleep after this drug. Its effect appears better than that of paraldehyde or urethan. It seems to be free from the disagreeable after-effects of chloral or opium. The sleep usually comes within twenty minutes after it is given. No ill effects were observed. There was mild intoxication in a few instances.

These cases are, of course, too few in number to draw conclusions from them as to the power of this drug. I believe it is not yet in our market and probably Dr. Williams has had the only specimen.

DR. ALBERT N. BLODGETT: It is in order I would like to say a word for paraldehyde, which has been mentioned in connection with the new drug presented to-night, and which has previous to this seemed to be the drug which has produced better results than any other of that character. Of course, when I say "of that character," I mean a drug which is a simple hypnotic and not a sedative like opium.

Paraldehyde has on several occasions, under my observation, produced a sleep which seemed to me more restful than that produced by any other hypnotic except perhaps urethan, and the latter seems to me less efficient, as it soon loses its influence, whereas paraldehyde seemed not to lose its efficiency. What pleased me most was the remarkable absence of after-effects after paraldehyde, which has been mentioned as pertaining also to this new drug. That seems to me to be an important advantage for we don't know how long it may be necessary to use it, and the use of other drugs might not be desirable. The nauseous taste of paraldehyde, and the eructations that rise after its use and the very great difficulty of mingling it pleasantly with other substances, are serious objections to its employment.

DR. WILLIAMS: This new drug does not seem to me to be as disagreeable to take as paraldehyde. That is one advantage which it has, and I think it is a rather stronger drug.

Adjourned at 10.15 o'clock.

PROCEEDINGS OF THE OBSTETRICAL SOCIETY OF BOSTON.

C. M. GREEN, M.D., SECRETARY.

DECEMBER 10, 1887, the PRESIDENT, DR. WILLIAM L. RICHARDSON, in the chair.

DR. J. G. BLAKE read a paper on

PROTRACTED GESTATION.¹

DR. BROWN asked the reader whether he had observed that nationality had any influence in protracting gestation. The reader replied in the negative: his own cases included three nationalities, — Irish, Italian, and German.

¹ See page 164 of the Journal.

DR. SINCLAIR queried whether shock might not cause protracted gestation: he quoted the case of a lady on shipboard, who at the expected time of labor was subjected to the shock incident to fire at sea, and whose gestation was supposedly thereby protracted one month.

DR. DOG remarked that both Müller and Villard deny the existence of prolonged pregnancy as a physiological condition; the former asserting that where it does exist, it is due to the pregnancy being extra-uterine; the latter explaining it as depending upon varying conditions of dystocia, or the existence of extra-uterine fetation, or the presence of carcinoma of the uterus, or atresia of the cervix. If they are right in their assertion why can not those cases reported by Dr. Blake as extending over 300 days, the child being born alive, be explained by the fact that fecundation of the ovum did not take place until just preceding the menstrual epoch first missed? Schroeder says that fifteen days may elapse before the union of the spermatozoa with the ovule takes place.

Now if the vaginal secretion is in a condition to allow the spermatozoa to live fifteen days, why not twenty, thirty or longer; or, in persons whose menses appear irregularly, why not until the following menstrual period. Dr. Arnold Thompson at the London Obstetrical Society, December 1885, reported the case of a woman who went 301 days from the time of the last coitus. The dates were absolutely certain, but the child was only of full average size and weight. I should think this case might be explained by supposing a prolonged duration of the menstrual interval, and that conception took place just before its occurrence. Dr. Tyler Smith believed in this theory, and Cederschild is reported as having observed cases of excessive prolongation of pregnancy where the menstrual interval had been unusually long.

DR. LYMAN said there was so much uncertainty about the time of fecundation, the occasional faithlessness of the wife adding also to this uncertainty, that it was practically impossible to fix the probable beginning of a pregnancy except when the husband is at home for only short, definite periods. In such cases the duration of pregnancy is approximately 280 days.

DR. GREEN said that as a woman might conceive just before a menstrual period and that period fail to appear, it was possible for a pregnancy to be apparently lengthened three weeks, — three weeks, that is, beyond the predicted time of labor calculated from the last appearance of the catamenia: he had frequently observed this apparent increase in the duration of pregnancy. In an actual protraction of the period of gestation he was not inclined to believe.

DR. RICHARDSON said that it always seemed to him strange that cases of so-called protracted gestation are being constantly reported; but one never hears of cases which, on almost the same weight of evidence, should be reported as so-called shortened gestation ending with an apparently fully matured child. He had often wondered whether the menstrual period of the individual might not have something to do with determining the period of gestation. The catamenia in most women occurs every 28 days, and the period of gestation corresponds to ten periods or 280 days. He questioned whether in women who menstruated every 26 or 29 days, for example, it might not be found that the period of gestation was 260 and 290 days respectively. Of course this is all the-

ory, but it would be interesting to see whether the period of gestation bore any relation to the catamenial period.

DR. J. P. REYNOLDS remarked that in the light of modern scientific investigation ovulation and menstruation cannot be supposed to have any necessary relation to each other: when they occur together, it must be considered a coincidence. In regard to the time of fecundation, the speaker had known instances in which married people believed that they had for a considerable period prevented impregnation by limiting intercourse to certain days of the intermenstrual interval; while later in the history of the family, this precaution ceased to insure immunity.

DR. C. W. TOWNSEND read, by invitation, a paper on

INCONTINENCE OF URINE IN CHILDREN,

of which the following is an abstract:

After reviewing briefly the physiology of micturition and speaking of the importance of investigating the cause in every case of incontinence, the reader gave the following list of causes:

I. Reflex.

- (1) Increased quantity of urine: (a) diabetes; (b) nephritis.
- (2) Irritant quality of urine: (a) increased acidity; (b) uric acid crystals; (c) calcic oxalate crystals; (d) excess of phosphates.
- (3) Vesical calculus.
- (4) Hypersensitive state of external genitals from: (a) stricture of urethra; (b) phimosis; (c) balanitis or vulvitis.
- (5) Anal irritation from: (a) pin worms; (b) eczema; (c) fissure.
- (6) Psychical.
- (7) Increased irritability of bladder.

II. Atony of sphincter vesicæ.

- (1) General debility.
- (2) Spinal disease.
- (3) Acute febrile disease.

III. Malformation of bladder or urethra.

Of 355 children, 179 boys and 176 girls, taken at random among the lower and middle classes, 77 or 21½ per cent. were found to be incontinent, the limit of normal incontinence being placed at three years. The majority of normal infants were found to stop wetting their clothes under one and a half years of age. Among the points brought out by an analysis of the 77 incontinent cases were: that 42 were boys, 35 girls, that in 47 the incontinence was nocturnal only, in two diurnal only, and in 28 both nocturnal and diurnal. In 63 incontinence continued from infancy; in 14 it came on after the primary incontinence of infancy had ceased.

In discussing treatment the uselessness and evil of corporal punishment in the majority of cases was spoken of. In regard to the operation of circumcision and breaking up adhesions between the corona and glans, its usefulness was recognized and cases cited, but it was not regarded by any means as always curative, for other causes might be operative. The investigations of Parks, who found more or less adhesions in 80 per cent. of boys under 9 years were mentioned as showing that adhesions are far from being always a cause of the trouble. Where no other cause could be found other than an increased irritability of the bladder, the use of belladonna in full doses till physiologi-

cal effects appear had generally been found to give satisfactory results.

DR. INGALLS had had cases of incontinence under all the heads mentioned by the reader: many associated with pin-worms, others with elongated prepuce, but very many kept up by the severity and cruelty of parents. His last case was in a boy nine years old, who had no mother and who slept with his father. The father beat the boy at night whenever the latter wet the bed. He had prevailed upon the father to discontinue his harsh treatment and had given the boy iron: in two weeks the incontinence had ceased.

DR. ABBOT had used choral successfully and also quinine.

DR. BLAKE had been successful with the bromides and with belladonna, of which latter drug children are very tolerant. It was his custom to begin with drop doses of the fluid extract, and increase until the physiological effects were manifested.

DR. ROTCH said that the reason more cases are not benefited is because a routine treatment is followed and the cause of the incontinence is not definitely discovered. Here as elsewhere careful diagnosis as to cause is essential to successful treatment.

DR. J. P. REYNOLDS had observed a case of incontinence of faces which continued several years: no cause could be ascertained and no treatment gave apparent benefit.

DR. F. B. HARRINGTON, a guest, said that when the cause of incontinence of urine is not mechanical, the belladonna treatment is very successful: he had given 30 minims three times a day to a child five years old, and had accomplished no curative result until that dose was gradually reached.

DR. CHADWICK had seen incontinence caused by masturbation in children two or three years old: he had used the bromides successfully in such cases.

DR. J. STEDMAN said a child should always be examined as to the state of the prepuce: when the prepuce was long, he had seen incontinence cured by circumcision. In other cases he had been most successful with belladonna pushed to its physiological effects: he thought bromides weakened children unduly.

DR. C. E. STEDMAN remarked that Dr. J. B. S. Jackson had pointed out that adhesion of the prepuce was a normal condition up to a certain age.

PULMONARY BLOOD-EMBOLISM (?) OR SHOCK FROM HÆMORRHAGE (?)

DR. C. ELLERY STEDMAN stated that he had received, in a personal letter from Dr. R. H. Fitz, the following opinion concerning the cause of the collapse after labor in the case reported by him at the meeting of October 8, 1887.²

"It seems to me after reading your remarks that the case was one of pulmonary embolism from blood-clot and not one of shock from previous hæmorrhage or exhaustion. Although there had been considerable hæmorrhage previous to your visit, the pulse was then but little affected. The pains were strong, delivery was prompt, and there was less loss of blood after delivery than usual. Although the pulse grew rapid during the half-hour after delivery there was no other evidence of disturbance; sudden weakness, dyspnoea, urgent demand for air, lividity, rapid and irregular

² Vide Boston Medical and Surgical Journal, December 8, 1887, page 555.

pulse were the symptoms of the attack, the intelligence being undiminished.

"Collapse from exhaustion or hæmorrhage is essentially a syncope with symptoms of arterial, especially of cerebral, anæmia: faintness, pallor, sunken features, sweating, sighing, slow breathing and restless movements are to be expected, and are of gradual approach except in sudden severe hæmorrhage. The classic symptoms of embolism of the pulmonary artery, on the contrary, are sudden, more or less intense dyspnoea, staring eyes, anxious expression, livid face, tumultuous action of the heart and feeble pulse. Symptoms of cerebral anæmia may occur later, but are not, as a rule, initiatory.

"The patient's condition favored a source of pulmonary embolism as it favored collapse from exhaustion or hæmorrhage; indeed there was no evidence of special exhaustion until the collapse occurred. Air-embolism seems less probable than blood-embolism, since the uterus was firmly contracted at the time of the shock."

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

EIGHTH-SECOND annual meeting, held at Albany, February 7th, 8th, and 9th.

FIRST DAY. — MORNING SESSION.

The President, A. L. LOOMIS, M.D., in the chair.

THE PRESIDENT'S INAUGURAL ADDRESS.

It contained a recommendation to the county medical societies to enforce the law against illegal practitioners, as had been done with such good results in New York. He thought the compromise bill regarding a board of medical examiners could now, if urged by united action on the part of the profession, be passed through the Legislature.

Regarding expert witnesses in medical matters, he thought questions propounded should not be formulated by lawyers ignorant of medical science, but by a court physician.

There was some disposition being manifest to establish county asylums for the insane. This was condemned by universal experience. He further recommended that a special committee be appointed to consider the advisability of placing quarantine in Government control.

He did not approve of the By-Law recently adopted looking toward the easy and rapid increase of membership of the Society, as it tended to increase the quantity at the expense of quality. The pharmacopœia was to be revised in 1890. This should not be left entirely to the deliberations of pharmacists, and he recommended appointing a special committee to consider aid in the labors from physicians.

He enumerated the losses by death during the year. The Committee on the President's Address consisted of Drs. Wey, Ford, and Daniel Lewis.

At the morning session, the Society was divided into a medical and a surgical section.

DR. KRETZSCHMAN, of Brooklyn, read a paper on

THE USE OF ALCOHOL IN CERTAIN FORMS OF FEVER.

Alcohol, he said, was a food, and also a medicine. It was the prince of antiseptics. It was especially useful in diphtheria. The dose and frequency of ad-

ministration should not be left to the judgment of patients or friends. Among other diseases, it was useful in phthisis with fever.

NEURO-THERAPEUTIC MEMORANDA.

DR. J. LEONARD CORNING, of New York, in this paper, described minutely the manner best to make medicinal injections, as solution of strychnia in tetanic spasms, in close proximity to the affected spinal cord, and cited some cases. Also treated of the benefits of the interrupted current in facial paralysis of rheumatic origin.

ON REFLEX NERVOUS DISTURBANCE.

DR. WILLIS E. FORD, of Rochester, referred to the contents of a former paper on a similar subject, which he had read at a previous meeting of the Society, and in this one spoke only of true reflexes, and not of conditions in which there was disease of the cord itself. His object was to show that the term reflex had been given too wide a range. He would no more speak of functional disease than of functional health. Any departure from health would get up a change in tissue sooner or later.

THE INFLUENCE OF OBESITY IN YOUNG WOMEN UPON THE MENSTRUAL AND REPRODUCTIVE FUNCTIONS.

DR. ANDREW F. CURRIER, of New York, read the paper. From personal observation and that of others, it was shown that obesity occurring in young women was usually attended by sterility. If the woman became pregnant, the offspring was likely to show inferior vitality. It was attended by disturbance of menstruation, the flow being absent or diminished in quantity and character; by pain, by vicarious menstruation, impairment of physical and mental powers, constipation, etc.

There was often a hereditary predisposition. Exciting causes were luxurious habits, inactive life, excessive sexual indulgence, use of too much fats, starches, and sugar.

Among other measures of treatment, he had been strongly impressed with the value of electricity, general and local.

DR. E. F. BRUSH, of Mount Vernon, read a paper on

BOVINE TUBERCULOSIS.

He commenced by remarking that after all discussions respecting tubercle, we are confronted with the question, "Is bacillary tuberculosis conveyed to the human race from animals affected with this disease?" He pointed out that of all domesticated animals the bovines were the most subject to tuberculosis, that indeed the human and the bovine races were preeminently tubercular. To no other animal do we owe so much for food and clothes as to the cow, and it would be strange if we did not acquire from her some malady. It is certain she did not acquire tuberculosis from us, for as Virchow points out, "Man is far more susceptible to animal disease than the latter to similar disease from man." The proportion of cattle infected with tuberculosis in England, is placed at five per cent., and increases, till in some of the thoroughbred Jersey herds of the Northern States, Prof. R. A. McLean declares that twenty per cent. are so affected. The reason why more human beings are not infected, is that the normal temperature in the human race is

so much lower than in the bovine, that the germ will not grow till the temperature is raised in the former to the degree naturally existing in the latter, namely 101° to 103° F. The same rule holds also in localized tubercular deposits where the temperature is raised by reason of injury to a degree permitting the growth of the bacillus. The cultivation of tuberculosis in other animals confirms this view, as the resistance to tuberculosis decreases in proportion as the natural temperature of the animal increases. Thus in the dog, with the lowest temperature, resistance is good, while in the common fowl with the highest temperature, resistance is nil.

The reader said further that the Federal Government had contributed half a million of dollars to stamp out pleuro-pneumonia which does not affect the human race, while tuberculosis, which decimates the human race, is left uncontrolled. He expressed the opinion that tuberculosis in man was derived from the bovine race, and pointed to the curious fact that where these animals are not domesticated, pulmonary phthisis is unknown. He said that if bovine tuberculosis were stamped out by means of laws regulating the breeding of the bovine race, it would soon become eliminated from the human race, and he was of the opinion that medical men should be instrumental in procuring the enactment of such laws.

DR. F. H. BOSWORTH, of New York, read a paper ON THE ACTION OF CAUSTIC APPLICATIONS ON THE NASAL MUCOUS MEMBRANE.

The caustic when applied to a limited area, buttoned down the mucous membrane, checked the inflammatory process, relieved the parts of their hyperæmic state. He had thus suddenly checked a "cold in the head" and relieved the patient of headache and other symptoms. He preferred chromic acid because its action could be definitely limited.

In the Section on Surgery, DR. HERMAN KNAPP, of New York, read a paper on

EXTRACTION OF CATARACT WITHOUT IRIDECTOMY, and gave a short report of one hundred successive cases. The results were remarkable in the amounts of vision obtained. Only one eye was lost out of the series.

DR. F. N. OTIS demonstrated new urethral and bladder instruments.

NOTES ON THE TREATMENT OF LUPUS.

DR. H. G. PIFFARD read the paper, in which he reported successful results in the treatment of lupus by applications of a solution of hydro-naphthol in liquor gutta-percha, and also by the use of hydro-naphthol in rubber plaster.

THE SURGICAL TREATMENT OF LUPUS.

DR. P. A. MORROW, in this paper, showed the advantage of treatment of lupus by multiple scarification.

RESULTS OF MECHANICAL TREATMENT OF 1,000 CASES OF HERNIA IN PRIVATE PRACTICE.

DR. W. DEGAIRMO gave a synopsis of 1,000 cases of hernia treated by mechanical means with an average result in all classes, of one in four cured. By cure he meant no return of the hernia, although the patient had gone without a support for six months.

AFTERNOON SESSION.

DR. CLARENCE C. RICE, of New York, read a paper on

REMOVAL OF LARYNGEAL GROWTHS WITH O'DWYER'S SNARE, IN COMBINATION WITH INTUBATION OF THE LARYNX.

The author described in particular the operation in children in whom it was one of the most difficult in surgery. In cases in which it did not endanger life, he renders the pharynx insensitive by cocaine, and then administered chloroform. O'Dwyer's snare required less skill for the removal of laryngeal growths than did the forceps and ordinary wire snare, and should be chosen by general practitioners.

DISCUSSION ON ACUTE BRIGHT'S DISEASE. PATHOLOGY AND CLINICAL HISTORY.

DR. FRANCIS DELAFIELD opened the discussion with a paper bearing this title. Notwithstanding the great amount of literature on Bright's disease, the subject had remained in an unsatisfactory and confused state. This had been due partly to the difficulties which of necessity attended its study, but largely to former methods of investigation. The kidneys had been looked upon too much individually instead of in their relation to the rest of the body. There had also been too much disposition to think of their function and not enough of their structure. The author began anew the study of kidney diseases three years ago, with much greater satisfaction than he had ever done before. On the present occasion he confined his remarks to acute Bright's. The cases were divided into three classes, namely, (1) the exudative; (2) parenchymatous or cellular degeneration; (3) diffuse nephritis. No matter what names were used, he thought we could group all cases of acute Bright's disease into three classes: (1) That in which the principal share in the morbid process was taken by the bloodvessels, and in which the principal evidences of inflammation were the matters exuded from the bloodvessels. Such a disease varied as to its severity but was regularly only a temporary lesion. (2) One in which the principal share in the morbid process was taken by the renal epithelium, and in which the evidences of inflammation were certain changes in the epithelial cells. Such a nephritis was regularly secondary to blood-diseases, and did not give constitutional symptoms. (3) One in which the principal share in the morbid process was taken by the stroma, and in which the evidences of inflammation were the growth of connective tissue in the stroma, with the addition of the lesion of exudative nephritis. Such a lesion was uniformly permanent and progressive, and was attended by well-marked constitutional symptoms.

ACUTE BRIGHT'S DISEASE OF CHILDREN.

DR. A. JACOB in this paper showed that acute nephritis was common in children, and was often overlooked, especially in the beginning when it was not attended by marked symptoms. In addition to examinations of the urine the temperature should be frequently taken after infectious diseases. The temperature of the surface was unreliable as an indication, it should be taken by the rectum. The first symptom usually noticed was œdema. The majority of cases in children were due to poisons of an infectious character, especially of scarlet fever and diphtheria. Neph-

ritis as a complication of pneumonia, occurred oftener in adults than in children. Cardiac affections other than those of rheumatic origin might cause nephritis by embolism and retardation of the circulation. Certain medicines would cause it. Sudden exposure to cold temperature frequently caused a serious form of Bright's, the patients often dying in from three to five days, with more or less suppression of urine.

CHANGES IN THE EYE IN ACUTE BRIGHT'S.

DR. D. B. ST JOHN ROOSA discussed this subject. Nothing really new had been added to our knowledge of it since Graefe wrote many years ago. When amaurosis or amblyopia occurred, nothing abnormal could be discovered by the ophthalmoscope. Was the amaurosis caused by poisoning of the blood or by sudden filling up of the cranial cavity, was a question for the pathologists. In some cases the pupils reacted, not in all. Förster concluded from this that the nerve-cells were not affected beyond the corpora quadrigemina. The amaurosis was usually recovered from. It had no peculiar treatment.

ON THE CARDIAC CHANGES IN ACUTE BRIGHT'S.

DR. RICHARD VAN SANTVOORD said hypertrophy, dilatation and cardiac exhaustion might occur secondarily in the acute as well as in the chronic malady. He was unable to say which gave out, the heart muscles or the nervous mechanism, or whether it was both. Certain conditions seem to point to failure in nervous mechanism as the prominent cause. The danger signal was a pulse of high tension. The indications for treatment were to diminish the pulse tension on the one hand and to strengthen the heart on the other.

ACUTE BRIGHT'S IN THE PUERPERAL STATE.

DR. FORDYCE BARKER discussed this portion of the subject. He used the term albuminuria of pregnancy, as the term "Bright's" frightened patients. In his experience, structural lesion did not exist except in a small proportion of cases previous to pregnancy in albuminuria of pregnancy; but they were allied affections and might coexist. He thought there was a condition in the bloodvessels in these patients which predisposed to albuminuria, which he spoke of as a super-albuminous condition. Perhaps under certain conditions the excess of albumen, if not absorbed by the fetal system, was returned as waste material and was one source of irritation. In one class of pregnant women the nutritive system showed inability to meet the increased demands upon it and the women became anæmic and hydræmic, while in others the nutritive system was stimulated to an overdegree and the women became plethoric. The albuminuria in these two classes required different treatment, the one tonic and nutritive, the other methods to reduce the plethora.

The symptoms were well known, but he might say they often began before albumen appeared in the urine, there being gastric and cerebral disturbance, œdema, etc.

Pilocarpin in albuminuria of pregnancy was dangerous. Abortion certainly should not be induced in all cases, for albuminuria of pregnancy occurred in about one of twenty-five cases, while eclampsia for which abortion was usually brought on occurred in fewer than one in four hundred. The irritation which it caused might, in fact, induce convulsions in a case in which they would not otherwise have occurred. He

cited two cases in which he had employed nitro-glycerin, that agent having apparently been the means of averting threatening eclampsia. It was continued in doses of $\frac{1}{100}$ grain.

THE TREATMENT OF ACUTE BRIGHT'S.

DR. WILLIAM S. ELY discussed this subject. The dietetic treatment was often so beneficial as to remove the symptoms and even prevent a diagnosis, especially if it were aided by inducing liquid stools several times a day.

When possible, such a simple plan of treatment as would give rest to the kidneys by causing the skin and bowels to temporarily do their work was advised. Liquid food, especially milk, was indicated. He agreed with Dr. Barker regarding the value of preparations of iron. He impressed the importance of treating each case individually.

DR. BARKER referred to a paper by Dr. T. R. Pooley, in which that gentleman had spoken of amblyopia and amaurosis as conditions indicating induction of premature labor, which obstetricians had overlooked. Dr. Barker had some years ago written of such affections of the eyes in the albuminuria of pregnancy, but they certainly should not in themselves be regarded as demanding induction of premature labor.

DR. DELAFIELD closed the discussion. He could not endorse the remarks of Dr. Barker to the effect that albuminuria of pregnancy should not be classed as one of the forms of nephritis. Autopsies had shown lesions in the kidneys in such cases which placed them in one or other of the divisions he had made.

INTUBATION OF THE LARYNX OF AN ADULT; EXHIBITION OF NEW INSTRUMENTS.

DR. JOSEPH O'DWYER read the paper, and presented specimens and instruments. He had personally practised intubation of the larynx in adults in four cases, three of which he had already reported. The first patient had intubation performed fifty or sixty times to overcome syphilitic cicatricial bands. Two of the other cases were also those of stenosis, due to contracting cicatricial bands originating in syphilis. The fourth case was one of diphtheria in the adult. One patient passed out of sight, and wore the tube ten weeks before returning. She had been more comfortable during that period than for some time before. In none had any pulmonary trouble developed from the entrance of food into the larynx and bronchi.

DR. WILLIAM HAILES, of Albany, read

THE HISTORIES OF SIX CASES OF INTUBATION OF THE LARYNX.

(To be continued.)

—The *Lancet* says that a child six years old, suffering from miliary fever was treated first with quinine administered in pilules and by inunction, and then by a subcutaneous injection of the alkaloid. One month later the fever had disappeared, but the child complained of pains in the left arm and at the point of injection; trismus supervened in three days, tetanus developed, and death occurred on the sixth day. If this was really a case of traumatic tetanus, the period of incubation was rather longer than the usual seven to fourteen days.

THE BOSTON
Medical and Surgical Journal.

THURSDAY, FEBRUARY 16, 1888.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States and Canada; \$6.00 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 94 Boylston Street.

All letters containing business communications, or referring to the publication, subscription or advertising department of this journal, should be addressed to the "Manager of the Business Department," Medical and Surgical Journal, 94 Boylston Street.

Remittances should be made by money-order, draft, or registered letter, payable to

CUPPLES AND BURD,
94 BOYLSTON STREET, BOSTON, MASS.

PROTECTION OF THE PURITY OF INLAND
WATERS.

THE special report of the Massachusetts Board of Health upon that part of their work which relates to the protection of the water-supplies of the State, appears in print as Senate document number four.

This duty of guarding the water-supplies of the State was placed in the hands of this Board by the General Court in 1886, and a generous appropriation of money was made by the Legislature in 1887. Thirty thousand dollars were given to the Board for the purpose of carrying out the provisions of the Act.

The present report gives an account of the work of the year 1887, divided into three sections.

First. Advice given to towns, corporations, and individuals in regard to appropriate sources of water-supply, the best way of preserving the purity of the same, and proper measures for the disposal of sewage.

Second. Collecting information in regard to all existing public water-supplies in the State, and arranging for such examination of these waters as may, from time to time, seem necessary.

Third. A review of the present state of our knowledge upon the subject of sewage disposal by irrigation upon land, or other means; and experiments for the purpose of adapting the results obtained in Europe to the conditions existing in Massachusetts, or of devising new methods more adapted to our surroundings.

The provisions of the Legislature, above referred to, are the first practical effort on the part of this State to secure the interests of the people, as a whole, against the limited interests of towns, corporations, or individuals. The Board's action upon the twenty-five applications for advice gives satisfactory evidence of the value of supervisory functions in the hands of a body removed from local influences.

The first application noted in the report is that of the city of Boston for advice in regard to taking the Shawheen River as an additional source of water-supply. In this case, the Board refused to advise the city to carry out the scheme for taking this river, and

gives its reasons at considerable length in a very complete study of the whole question of the water-supply of the metropolitan district for the next generation. While this JOURNAL has, on many occasions, called attention to the bad condition of the Mystic water system, and has had the support of the medical profession in so doing, we have recognized the force of the objections to the Shawheen River plan, and commend the thoroughness of the Board's examination of this very serious problem.

The Board appears to have committed itself to the recommendation of intermittent filtration as a plan for the treatment of the sewage of Brockton, and has offered the same advice to other towns and some public institutions.

Alewife Brook, which the city of Cambridge, with the help of a hog-slaughtering establishment, has turned into a disgusting sewer, receives the following notice from the Board: "The public health requires that such an open sewer should not exist, and the means of relieving the public of this nuisance are a part of the problem of disposal of the Mystic River sewage which the Legislature has referred to this Board, and which is now being actively considered."

The plan for examining public water-supplies promises useful results. The chemical analyses, under Professor Drown's charge, are accompanied, so far as possible, by a study of the animal and vegetable life always present in surface water. Mr. Parker, S.B., Assistant in Zoology in Harvard University, and Dr. E. K. Dunham, have the direction of this portion of the investigation. As not quite six months have elapsed since work was fairly begun in this direction, the Board wisely abstains from entering upon a general discussion of the analysis already made. Many interesting facts are, however, stated, and some suggestions made, for which our readers are referred to the report.

Under the third head — the treatment of sewage — a very encouraging amount of original work appears to have been done, and the question of the disposal of sewage by intermittent irrigation on land bids fair, at last, to become the subject of a scientific examination of authority sufficient to replace the confident assertions of one side, and the equally positive denials of the other, with which the advocates of rival systems have tired the ears of a public for a generation.

One conclusion already arrived at is this: that desirable as the use of sewage in broad irrigation may be, yet this kind of irrigation cannot be depended upon in the more closely settled parts of the State; if irrigation is used in such localities, it must be used in the form of intermittent filtration.

A very complete experimental station has been established at Lawrence, where land owned by the Essex Company was placed at the disposal of the Board. Ten tanks of cedar have been constructed, with all the necessary apparatus for measuring fluids; each tank is five feet deep, and has a superficial area of the two-hundredth part of an acre. These tanks

are filled with various soils, which may be varied from time to time, so as to represent any given locality. In addition to these, a third of an acre has been properly prepared for the purpose of receiving sewage directly, and studying the effect. Sewage is conveyed to this station by pipes from the public sewers of the city. A small, but well-equipped chemical laboratory has also been provided, so that all the required analyses may be promptly made. A large part of the report, under this head, is taken up with an interesting series of observations upon the changes effected in the water of the Merrimac River while passing through the different soils in the tanks. These observations appear to bear strong testimony to the value of properly constructed filter-beds for the purification of water-supplies.

The Board, in conclusion, asks for an appropriation of \$25,000 to carry on this work; and it is a satisfaction to know that the proper Committee recommended the amount to the Legislature, which has already, we believe, passed the necessary appropriation bill.

The Board of Health has also sent to the Legislature a report of progress upon a matter of especial consequence to Boston and its vicinity, the definite plan for the drainage of the valley of the Mystic, and of so much of the Charles River as it may seem advisable to add thereto. This very brief report is a bare statement of progress made in the study of the subject, but, like the document noticed above, gives promise of results that shall have a foundation in actual experience. If the Board succeeds in presenting a plan that provides for a satisfactory disposal of the sewage in this important part of the metropolitan district, by means generally approved by experts, then the sum of \$14,000, which is required to complete the task of examination, will be no exorbitant price for the service rendered.

It will be remembered that Governor Ames, in this year's inaugural address, expressed himself very decidedly in favor of the investigations carried on by this Board in the directions above noticed, and with sound common sense concluded: "The fact that answers to these troublesome questions of water-supply and sewage-disposal can only be given by experts, makes it almost necessary that this advice should be furnished by the State under conditions of complete impartiality."

ANNUAL REPORT OF THE HARVARD MEDICAL SCHOOL, 1886-87.

FROM the report of President Eliot and of the Dean of the Medical School, as contained in the last annual report (1886-87) of the President and Treasurer of Harvard College, we take the following statements: The report of the Committee of nine, appointed by the President, to consider in all its relations the general subject of shortening the college course in favor of the professional schools—a point brought forward in the Academic Council last November—is

still under advisement by the Council. We hope some definite step may be taken at a not very remote date.

In this connection, it is well to note that the number of students in the fourth year class of the medical school has fallen back to about what it was in the first years of the experiment (1880-81-82-83); namely, 10, and the President calls attention to the following table, which, he says, "reveals some of the difficulties besetting the interesting experiment":

	1880-1.	'81-2.	'82-3.	'83-4.	'84-5.	'85-6.	'86-7.	'87-8.
4th Year Class	9	9	10	12	16	18	21	10
Applicants for the 4th year degree	4	9	6	11	6	9	11	..
Of whom there were rejected	4	0	0	3	2	2	6	..
Of whom there received <i>cum laude</i>	0	5	2	2	2	1	5	..

In plain words, it appears in the first place that not one-half of those who take the fourth year course apply for the fourth year degree. Secondly, the percentage of rejection at the examinations for the fourth year degree is so large that prudent students may well prefer to take the third year degree at the regular time, rather than to run the risk of having to fall back upon it after failing to get the fourth year degree. During the past four years, the percentage of rejection for the fourth year degree has been 35 per cent., while the percentage of rejection for the third year degree has been only 16½ per cent. Thirdly, it is evident that there have been two sorts of students in the fourth year class: one sort, the most promising men in the school; the other sort, men who need four years of study in order to obtain the third year degree. The number of examinations which the student was expected to pass at the end of the fourth year has been unreasonably large.

The experiment as a whole is not yet successful; and such inferences as can safely be drawn from it do not encourage the hope that a fourth year of study can soon be demanded of all candidates for the degree of Doctor of Medicine, unless, indeed, the school shall receive a special endowment to enable it to take this costly step.

We are glad to note a definite statement to the effect that the school is very inadequately endowed, the natural inference from last year's report being rather the reverse. The Dental and Veterinary Schools are also sorely in need of endowments. In regard to the Medical School, the Dean says:

"With the increased development of its teaching facilities, the need of endowed professorships is every year more and more plainly felt, and it is to be hoped that before many years the school will be enabled through the generosity of its friends to arrange its curriculum without constant reference to the pecuniary returns derived from students' fees."

The whole number of students in attendance during the year was 282; during the first term, 273; during the second term, 264. Of these, 164 had literary or scientific degrees. There were 87 applicants for the degree of Doctor of Medicine in the three years' course, of whom 11 were rejected.

THE ROBINSON POISONING CASE.

THE case of Sarah J. Robinson, whose trial, for the murder of her brother-in-law by the administration of arsenic, took place last week in Cambridge, is, so far as we remember, without a parallel in the annals of toxicology in this country. The prisoner was indicted for the murder of seven persons: her landlord, husband, sister, brother-in-law, daughter, nephew, and son, in the order given.

The first of these deaths took place in August, 1881, the last in August, 1886. All died with the usual symptoms of arsenical poisoning. It is now said that there were suspicious facts connected with the deaths of all: but suspicion was not so far excited as to lead to an investigation till the sickness of the son, the last in the list of her alleged victims, which took place in August, 1886. At this time, the suspicions of the officers of the lodge in which the lives of the members of her family were insured were excited, and, as a consequence, the attending physician, who had already recognized the possibility of poisoning, procured an analysis of the vomitus, and the true nature of the sickness was soon disclosed. The prisoner was arrested August 11, 1886, the day preceding the death of her son. Arsenic was found in the body of the son. Then, one after another, the bodies of those mentioned were exhumed, and the organs submitted to analysis, with one uniform result: arsenic in all. It was discovered, in the course of the investigation, that some embalming fluid (the name of which could not be ascertained) had been injected into the body of the sister. Most of these fluids contain arsenic as one of their ingredients; and as it is well established that arsenic injected in this manner after death may find its way by diffusion into all the organs of the body, even the brain, it was manifestly impossible for the chemist to say that all the arsenic present might not have come from the embalming fluid. The sister died, however, with symptoms which were consistent with those of acute arsenical poisoning, and circumstances pointed to the prisoner as the author of the crime.

The prisoner was tried in December last for the murder of her son; but the jury disagreed, the understanding being that they stood 11 to 1 in favor of acquittal. The trial just concluded was upon the indictment charging her with the murder of her brother-in-law. Nothing of interest from a medical or toxicological point of view was brought out at this trial. The medical and chemical testimony showed conclusively that death was due to arsenical poisoning. The evidence against the prisoner was wholly circumstantial. It was not shown that she had bought arsenic, or that she ever had any in her possession, or that she knew anything about arsenic. The Government based their case upon her actions and words, and upon the fact, as they claimed, that she was the only person who had the opportunity to administer poison, or any motive in administering it. The alleged motive was to gain possession of an insurance

of \$2,000 on the life of her brother-in-law. Evidence was offered tending to show that the prisoner was in straitened circumstances, and obliged to borrow money at high rates of interest, mortgaging, for this purpose, the same property to two or three different persons under assumed names. The money thus borrowed was repaid immediately after her receipt of the insurance on her brother's life, and presumably from the proceeds of this insurance, which she had claimed, falsely, as it proved, to have invested for her nephew.

The defence did not deny the fact of arsenical poisoning, but claimed that the arsenic might have been administered by accident or that it might have been taken with suicidal intent. The jury, however, failed to coincide with either of these views, and returned a verdict of guilty in the first degree.

Mrs. Robinson has been found guilty on one indictment only. Assuming that she is guilty of all she has been charged with, her remarkable success as a poisoner cannot be attributed to any special skill on her part. She is a woman from the lower ranks and evidently illiterate. She employed the most common of poisons, and all the cases appear to have presented the symptoms usually observed in cases of arsenical poisoning. The alleged motive in at least four of the cases was an insurance of \$2,000 on the lives of the victims. Her success appears to be in part attributable to the failure of the attending physicians to recognize the true nature of the earlier cases; or, if the possible character of the sickness was recognized, as appears to have been the case in certain instances, a failure to pursue the one course which would doubtless have led to the true conclusion, namely, to procure an analysis of the vomitus or excretions. This much should be said, however, in this connection, that the cases occurred in two or three different cities and were under the care of different physicians, so that suspicion was not excited through any recollection of similar cases occurring in the same family. Her success was also doubtless favored by her remarkable ability to so conduct herself that no suspicion aside from those suggested by the symptoms, should be excited; an ability which all who witnessed her remarkable self-possession during the two trials which she has undergone, will probably concede to her. The case has naturally excited much interest in this vicinity and finds a parallel, in more recent times, only in such cases as those of Anna Zwanziger and Margaret Gottfried, which occurred on the continent of Europe in the earlier years of the present century.

In conclusion, we have to express our regret that poisoning by arsenic is rendered so easy in this Commonwealth by the fact that such preparations as "Rough on Rats," may be, and are, sold without any restrictions whatever.

—Salicylate of bismuth has been found by Solger to be effective in many rebellious cases of chronic diarrhœa. It is given in doses of eight to ten grains, three times a day, to a child of three years, and its effects are attributed to its antiseptic action.

MEDICAL NOTES.

— Tracheotomy was successfully performed upon the Crown Prince of Germany, at San Remo, February 9th.

— One of the handsomest of the new exchanges which has come to us is the *Chugai-Ijishimpo*, a Japanese and foreign medical journal, which is published in Tokyo. Typographically and pictorially, it is an object of beauty, and if its scientific character equals its looks, which fact we are obliged to accept on faith, it is certainly a most useful aid to practitioners of medicine in that country.

— At the Sixteenth Congress of the Society of Surgery of Berlin, Sir Spencer Wells and Professor Billroth were elected honorary members, 142 members voting. The former received 137 votes, 14 voting for him only; the latter 123, one voting for him only.

— An English Rear Admiral recently committed suicide in a manner unique in the annals of medical jurisprudence. While in the drawing room with his wife after dinner, the lady was playing to him on the piano when he heated a thin brass poker to redness in the fire, and thrust it, so heated, into his abdomen, inflicting four wounds of which he died the same night.

— Mice are said to evince a clearness of discrimination in deciding between butter and oleomargarine, which it would be well in some cases if public examiners could attain. They will eat butter *con amore*, but they will not consume any of the cunningly prepared greases, it seems, except under protest.

BOSTON AND NEW ENGLAND.

— The month of January last presented the largest mortality of any January in the history of the city. The deaths were 1,043, against 836 in January 1887. Consumption caused 139 deaths, bronchitis 60 and pneumonia, 192. The deaths from pneumonia in January 1887, were but 95. Steady cold such as prevailed last month certainly has a very depressing effect on the vital forces. 33 deaths were returned as from old age.

— The thirteenth annual report of the Salem (Mass.) Hospital is issued, showing the number of patients admitted to the hospital during the past year to have been 247. Of these 105 were medical, and 142 surgical; 120 were males and 127 females. The average number of days passed in the hospital by free patients was 29.3-4, and by those paying board 23.1-4. Board was furnished to free patients 6013 days, and to those paying board 790 days. The Boston and Maine Railroad bed was occupied 170 days, the Naumkeag Mill's 46 days; and 62 days' board was furnished to United States Marine patients. The largest number of patients in the house at any one time was 30, the smallest 16. The average cost per day for each patient was \$1.40. The total income from investments, the payment of board, etc., was \$39,504, including a legacy of \$13,500. The ex-

penses including investments of nearly \$18,000, were \$33,000, leaving a cash balance in hand of \$6,600.

— The Merchants Club—a body of prominent Boston merchants who dine together once a week, and have the custom of inviting representative men of the different important professional and commercial interests to partake of their hospitality—entertained the medical profession last Thursday evening at a handsome banquet at the Parker House. After dinner, President Richard T. Briggs called to order, and the Secretary, Mr. B. F. Guild, of the Commercial Bulletin, read what might be called comic records of the preceding meeting, which sparkled with bright points; though perhaps not true records, they were certainly amusing.

The members of the club then listened with apparent interest and courteous attention to a statement of the present status of surgery and obstetrics as compared with former times, of the present condition of medical education as exemplified by the Harvard Medical School, of the past and present condition of the Massachusetts General Hospital and of the Boston Lying-in Hospital and of the claims of these institutions upon the generous financial support of the merchants of Boston, as set forth by the medical speakers.

Dr. H. P. Bowditch spoke for medical education and the Harvard Medical School, Dr. D. W. Cheever for modern surgery, Dr. C. B. Porter for the General Hospital, Dr. W. L. Richardson for the Lying-in Hospital. Dr. F. W. Draper spoke of the relation of the profession to the public in the courts and in inquests, and the editor of the JOURNAL responded for the Medical Press. Speeches on general subjects were also made by Drs. H. W. Williams, G. H. Lyman, J. P. Reynolds and J. Collins Warren.

About one hundred gentlemen sat down at the tables, and the occasion was one of much enjoyment, as it is hoped it may prove of mutual profit. Among the medical men present besides those mentioned were Drs. E. N. Whittier, A. T. Cabot, M. H. Richardson, S. W. Langmaid, S. J. Mixer, O. B. Shreve, R. H. Fitz, J. W. Pratt and others.

Miscellany.

DESTRUCTIVE ACTION OF BOILING WATER ON TYPHOID BACILLI.

In order to test the destructive power of boiling water on typhoid bacilli, Dr. Vilchur, of St. Petersburg, according to the *Lancet*, made a number of pure cultures in broth, keeping them in a thermostat for two days at a temperature of about 33° C., and then mixed them with known proportions of boiling water, immediately afterwards sowing the mixtures in jelly. The results showed that, when the volume of boiling water equalled that of the culture, the bacilli were partially, but not wholly destroyed. When double the volume of boiling water was used, the bacilli were all killed. From experiments with typhoid stools, he found that all the bacilli, however numerous, were invariably destroyed by the addition of a volume of

boiling water equal to four times that of the stool. In this way, he suggests it will be easy to disinfect with certainty all the dejections of typhoid patients.

ILLE OLIM MEMINISSE JUVABIT.

THE following extract is from the letter of a New York correspondent, a famous practitioner of many years' experience :

"What interesting letters those are from the pen of Brother Cotting! I have gone over so much the same ground—*haud passibus æquis*—that it seems to me I am reading my own experience. I never shall forget, years and years ago, how astonished Brown-Squard was when he read some trifles I had written for a non-viable medical journal, to show that pneumonia had, under certain conditions, a natural tendency to recovery, and how little 'heroic' treatment had to do, except in an undesirable way, in any case.

"Dr. Cotting's stories please me hugely. One of them recalled the following experience of my own :

"In the early days of anesthesia, I had quite a reputation as a giver of ether and chloroform. One day, a distinguished surgical friend asked me to give the anæsthetic for him to a great and rich General, whom he had promised to castrate for malignant disease of the testis.

"I kept my appointment, and found the instruments arranged in order, the operating table ready, and the warrior eager to have the ill-behaved gland removed. Out of courtesy, I was asked 'to look at it.' I happened to know the clinical history of the patient, and soon satisfied myself that syphilis had claimed him for her own in a constitutional manner, and that trenchant steel was not what he most needed.

"I so told my brother doctor, who, being a noble, conscientious man, made an excuse to defer the ablation, put the son of Mars upon the appropriate treatment, and completely cured him. In the course of time, my 'gentle reminder' found its way to the hero's hand. Looking at it for some minutes, he said : 'What a ——— outrage! That man just came to give me ether. It was found best by my surgeon to put off the operation, and Dr. M. didn't even give me the anæsthetic. He simply wasn't wanted, and went home. He must think I'm made of money, d—— him!'"

STONE IN THE STOMACH.

CONCRECTIONS, or stones, are not often found in the human stomach, though the bezoar of the abomasum and intestines of ruminants is well known, and in olden days was very highly esteemed as a remedy against poisons and infectious diseases, being even worn as a charm. Human intestinal agglomerates are occasionally found in oatmeal-eating districts, and have sometimes been dignified by the name of "avenoliths." An enterolith was found by Langier in a human subject, the nucleus of which was formed by a piece of liquorice root. True gastricoliths are, however, occasionally found in human stomachs; thus Schönborn was able to collect seven such cases, all of which appeared to have formed round a nucleus of hair; one of these weighed two kilogrammes. Quite

recently a Dutch physician, Dr. H. A. Kooyker, has described a case of a true gastric concretion weighing 885 grammes, in which there was no nucleus at all. The patient was a middle-aged man, who was so averse to examination and manipulation of all kinds that it was very difficult to form a diagnosis of his disease. He occasionally vomited blood, and gradually became more and more emaciated. A tumor was felt in the epigastrium, but its nature was not made out until the post-mortem examination revealed a stone measuring eighteen by eight centimetres, nearly filling the cavity of the stomach. There was also a smaller stone situated at the pyloric extremity. These stones were of a brownish color, and the large one contained several cavities. It had an offensive smell like that of feces. A number of vegetable cells were found in it, but it was devoid of concentric or other structure. It does not seem to have been fully analysed. — *The Lancet*.

STRYCHNIA AS A HYPNOTIC.

DR. T. LAUDER BRUNTON in the *Practitioner* for January narrates his favorable experience with this drug. After alluding to the unfortunate results of the use of opium and chloral for inducing sleep, he says :

"In treating some cases of persons engaged in literary work who were suffering from sleeplessness and yet were obliged to have their brains perfectly clear during the day, it occurred to me that if I could convert the condition of over-tiredness into a condition of simple tiredness, the patient would naturally fall sound asleep without the use of any hypnotic. One can sometimes do this to a certain extent by giving some warm beef-tea or a teaspoonful of Valentine's meat juice in water either hot or cold, or by giving a little alcoholic stimulant, such as whiskey and water or brandy and water. It is probable that these substances have a double action, tending to dilate the vessels of the stomach and withdrawing blood from the head, as well as tending to exert what we may vaguely term a stimulant action on the nervous tissues themselves, without understanding what the exact nature of this stimulant action is. It occurred to me that as strychnine is one of the most powerful stimulants, if not the most powerful nervous stimulant that we possess, a small dose of it might have the effect of bringing the depressed nervous system up from the condition of over-fatigue to that of simple fatigue, and thus inducing sleep. I accordingly tried it, and was much pleased with the result. It acted exactly in the manner that I expected, and induced comfortable healthy sleep without any disagreeable effects next day. The way in which I have used it has generally been either in the form of the tincture of nuxvomica in doses of 5 to 10 minims or in the form of Schieffelin's granules, containing $\frac{1}{100}$ of a grain of sulphate of strychnine in each. One, two, or more of these granules were given at bedtime, and the dose was repeated if the patient happened to awake within one or two hours afterwards."

The author thinks it is very doubtful indeed whether strychnine would answer in other cases of sleeplessness than those arising from overwork or worry, and more especially from overwork. He has tried it, however in a case of sleeplessness occurring in anæmia, but as the patient at her next visit complained that

the medicine made her sleep rather too heavily, he is not quite sure how far mere suggestion may have played a part in effecting the result, and indeed admits that he cannot exclude this factor in some of the other cases, a factor which needs to be remembered as possibly operative in all experiments with new remedies.

"ABOUT THE SIZE OF A —"

AN "English physician who reads and values American periodical medical literature" writes to the *Philadelphia Medical Times* an entertaining, and at the same time, most apposite protest against the loose way in which physicians on both sides of the water describe the size of pathological objects. It is a point upon which this JOURNAL has already touched editorially, but it will bear repetition. The writer says:

"Such time-honored comparisons as a 'fœtal head' (I thought they varied a great deal) or 'a millet-seed' (I never saw a millet-seed, but I believe it to be about as big as a miliary tubercle), we cannot hope to get rid of before the millennium. But when it is a mere matter of length or breadth, could we not state the fact in inches or millimeters? I am moved to write to you by having been just now brought up by the statement that something or other was 'about the size of a dollar.' I was interested in this case up to that point, but I got lost then; the

only dollar I ever saw was a tiny gold coin, 'about the size of a three-penny bit'; I beg pardon, about fifteen millimeters in diameter. From the context, I think that the article mentioned must have been bigger than that, but I am not sure, and the statement bewilders me and destroys my interest in the case. Another time, I came across the statement that a tumor was 'about the size of a doughnut.' Now, as to a doughnut my mind is blank; is it a nut that grows on a tree—a coconut, or a walnut, or a hazelnut? or is it the other half—'dough' suggests it is a kind of cake—a 'bath-bun,' or a 'tea-cake,' or perchance, a cake 'about the size of a piece of chalk?' as the witness said in the famous trial.

"It is bad enough, Sirs, to have to learn two or three languages in order to keep ahead of the progress of medical science. Why should we, who speak the same language, throw these entirely unnecessary obstacles in each other's way? I hope you will lend your powerful influence to induce our American cousins to give their measurements in terms of some scale which can be mutually understood."

The writer adds in a postscript:

"P. S.—Since writing the above, a lady has told me that a 'doughnut' is a kind of bun about the size of an orange, brown outside, jam inside, very good to eat, and 'they cost three half-pence.' Upon this I wish to ask: (1) Tangerine or Seville orange? (2) Is she right? (3) Granting 1 and 2, is this a satisfactory way of arriving at a pathological fact?"

REPORTED MORTALITY FOR THE WEEK ENDING FEBRUARY 4, 1888.

Cities.	Estimated Population.	Reported Deaths in each.	Deaths under Five Years.	Percentage of Deaths from

Deaths reported 2,383; under five years of age 820; principal infectious diseases (small-pox, measles, diphtheria and croup, diarrhoeal diseases, whooping-cough, erysipelas and fevers) 320, acute lung diseases 420, consumption 327, diphtheria and croup 128, scarlet fever 45, diarrhoeal diseases 36, typhoid fever 23, measles 25, whooping-cough 16, puerperal fever 15, erysipelas nine, malarial fever nine, cerebro-spinal meningitis eight. From typhoid fever, Philadelphia 14, Baltimore four, Lawrence three, New York and Milwaukee two each, New Orleans, Nashville, Charleston and Lowell one each. From measles New York nine, Baltimore seven, District of Columbia five, Milwaukee two, Boston and Pittsburgh one each. From whooping-cough, New York, Baltimore and Pittsburgh three each, Philadelphia two, Boston, Lowell, Springfield, Somerville and Waltham one each. From puerperal fever, Milwaukee five, New York four, District of Columbia three, Philadelphia, Baltimore and New Orleans one each. From erysipelas, New York seven, Philadelphia two. From malarial fever, New York five, Philadelphia two, Baltimore and New Orleans one each. From cerebro-spinal meningitis, New York three, Baltimore two, Milwaukee, Worcester and Fall River one each.

In 20 cities and greater towns of Massachusetts with an estimated population of 1,044,166, the total death-rate for the week was 23.15 against 25.16 and 23.87 for the previous two weeks.

In the 28 greater towns of England and Wales with an estimated population of 9,398,273, for the week ending January 21st, the death-rate was 25.0. Deaths reported 4,145; infants under one year of age 847; acute diseases of the respiratory organs (London) 531, whooping-cough 115, scarlet fever 85, measles 56, fevers 50, diphtheria 36, diarrhoea 29, small-pox (Sheffield) 25, Bristol three, Nottingham two) 30.

The death-rates ranged from 17.0 in Brighton to 28.8 in Portsmouth; Birmingham 21.0; Bradford 19.5; Hull 18.1; Leeds 19.2; Leicester 19.2; Liverpool 21.6; London 24.4; Manchester 26.8; Nottingham 25.3; Sheffield 25.0; Sunderland 20.2.

In Edinburgh 23.8; Glasgow 23.3; Dublin 32.9.

The meteorological record for the week ending February 4, in Boston, was as follows, according to observations furnished by Sergeant O. B. Cole, of the United States Signal Corps:—

Week ending	Barometer.		Thermometer.		Relative Humidity.			Direction of Wind.			Velocity of Wind.			State of Weather.			Rainfall.

ON THE DANGERS OF SIMPLE EXTRACTION OF CATARACT.

BY BASKET DERRY, M.D.

THE question as to what operation should be performed in an ordinary case of senile cataract is once more a prominent subject of discussion. At the late meeting at Heidelberg, as well as at the one held at New London, this matter engrossed much attention. More recently, Professor Schweigger, of Berlin, has published in Knapp's "Archives" an article on the return to the flap operation, in which the performance of iridectomy, the "needless maiming of the iris," as the author expresses it, is strongly denounced.¹

Up to within a very few years, there has been but one form of extraction practically in vogue, the operation of Graefe, modified from the method originally laid down by the master by the departure from a linear cut, and the formation of a flap of appreciable height, but following his teaching in the routine removal of a portion of the iris previous to bringing about the expulsion of the lens. This is the only operation concerning which extended statistics have been published since the flap operation became obsolete; the methods of Liebreich and Lebrun having never met with general favor. They were supported by no reliable or extended tables of results, and the healing process after their performance was found to be attended, in many instances, with disagreeable complications.

One great drawback to the former flap method was the danger of corneal suppurative. Graefe's operation was much less liable to this complication; but besides this, two minor, though serious evils were largely obviated. The removal of a segment of the iris not only lessened the danger of prolapse, but, by exposing a large pupillary area, enabled the operator to ascertain the presence of, and generally to remove the fragments of cortical substance often left behind by the lens in its passage through the external wound. Other advantages of the new operation were the greater freedom of motion allowed the patient during convalescence, and the shortened period of after-treatment.

The almost universal abandonment of the corneal flap without iridectomy for the method of Graefe, first brought forward twenty-three years ago, was influenced not only by the above advantages, but also by the improved statistics. Those given by Graefe himself in 1863 were as follows:

After Flap Extraction (1,000 cases).²

Complete success	80 per cent.
Partial success	12 to 15 per cent.
Failure	5 to 8 "

After the New Method (600 cases).³

Complete success	90.1 per cent.
Half success	6.8 "
Failure	2.8 "

Dr. Knapp has just given us his own results in 1,000 cases operated on according to the method of Graefe:⁴

Good Results	85.4 per cent.
Moderate results	8.5 "
Failure	6.3 "

¹ Archives of Ophthalmology, Vol. XVI, p. 455.² Klinische Monatsblätter, 1868, p. 14.³ Klinische Monatsblätter, 1868, p. 17, note.⁴ Trans. Am. Ophth. Soc., Vol. IV, p. 422.

The statistics of simple extraction, the operation now proposed as the standard, are as yet limited. Schweigger reports 62 cases, no table of results being given.⁵ Knapp has operated 68 times, with 2 total failures, protrusion of the iris in 3 cases, incarceration in 2.⁶ Bull gives 24 cases of hard, senile cataract thus treated. These were all successful, although prolapse of vitreous occurred three times, the lens having to be removed instrumentally, and a secondary operation was necessary in 7.⁷ With such a paucity of observations, it is evident that any objections to the new method must be somewhat based on theoretical considerations.

As has been said, the two principal dangers after flap extraction were corneal suppurative and prolapse of the iris. The former of these would be lessened by a diminution in the height (and thereby extent) of the flap, and the employment of antiseptics; the second by the use of eserine, and the substitution of cocaine for the administration of ether or chloroform, at once avoiding the pain of the operation, and the dangerous strain on the eye incident to retching and vomiting. The question at present under discussion is, therefore, the following: Do the modern discoveries of a reliable myotic, of an efficient local anæsthetic, and the adoption of antiseptics, justify a return to the principle of extracting senile cataract without the performance of iridectomy?

At the New London meeting, Dr. Knapp expressed himself as follows: "On the whole, I may say this, that the so-called simple method of extraction seems to me as safe as that with iridectomy."⁸

I have been enabled to collect the notes of 48 cases of simple extraction performed in Boston within the last three years, all but three of them at the Eye Infirmary, and nearly all having occurred in the practice of two surgeons of that institution, both of whom had had a large experience in the Graefe operation. Of these 48 cases:

Central, movable pupil was left behind	31 times.
Pupil remained drawn slightly upward	5 "
Hernia of the iris occurred	12 "
Vision of one-tenth and more was gained in	40 cases.
Moderate success	5 "
Perception of light remained in	2 "
Still under treatment	1 "

These figures, it is true, cover but a small number of cases, and, as far as they go, compare most unfavorably with any that have as yet come under my notice. It is but right, however, to publish them as a definite record of experience. Doubtless a greater familiarity with the operation of simple extraction will diminish the percentage of accident. It will be observed that there was no case of absolute failure, as the patients who left the Infirmary with perception of light may subsequently be restored to sight by the performance of an iridectomy. My object is not to decry the operation performed, but to call attention to the main difficulties experienced in the performance and encountered in the after-treatment.

One familiar with the method of extraction, according to Graefe, need meet with no special difficulty in the performance of the preliminary steps of simple extraction. Using the narrow knife, the correct completion of the cut, without wounding the iris, demands, of course, a quick eye and a steady hand.

⁵ Loc. cit., p. 453.⁶ Loc. cit., p. 419.⁷ Trans. Am. Ophth. Soc., Vol. IV, p. 48 (table following).⁸ Loc. cit., p. 426.

With appropriate manipulation, the lens is made to readily emerge. But unless the crystalline has escaped entire, the removal of *debris* from the field of the pupil is certainly much more difficult than when an iridectomy has been performed. Professor Becker called attention to this fact in his remarks at the Heidelberg meeting, and laid stress on the increased facility with which the pupil might be examined and cleared over the region where an iridectomy had been performed.⁹

To this it may be replied that, by restricting the performance of simple extraction to cases in which the cataract is mature, the nucleus large, and but a small amount of soft cortical substance probably present, the danger of leaving portions of the lens behind is reduced to a minimum.

Such cases are, however, equally liable with others to the second danger that attends simple extraction, that of prolapse of the iris. This accident occurred twelve times with us out of 48 cases, an unusually large percentage, it is true, when compared with the results elsewhere published. And in speaking of the danger of prolapse of the iris, I do not refer to what may take place at the time of the operation. In most instances, after the cataract has been removed, the iris can be replaced, and the usual direct application of eserine made. Should the prolapse at this time persist in recurring, it is easy to excise it on the spot. The serious forms of this accident are those in which it occurs some time after the operation, without apparent cause, and without giving rise to any symptom of its presence.

Two such experiences are here given. Simple extraction had been performed on a female, aged forty-nine; the lens had emerged in its capsule, leaving a clear, black pupil, and the iris had gone back perfectly into place. Eserine was instilled, and the eye banded. On the fourth day, without any apparent cause, sudden and severe pain came on in the eye, and a large prolapse of the iris was found to have taken place. This was subsequently excised and a vision of five-tenths obtained, though at the cost of a somewhat tedious convalescence. The other patient was a woman of sixty-five, from whose eye a large, mature cataract had been removed without iridectomy, a clear pupil being left, and the iris resuming its natural position. As usual, eserine was instilled. The patient was perfectly quiet and docile, made no violent movement, experienced no subsequent pain, and had no swelling of the lids; and yet the removal of the bandage on the seventh day disclosed a large prolapse. In this, as in the other case, excision of the iris had to be performed, and the recovery was tedious. Both would probably have done better had the operation of Graefe been performed.

I call attention to these cases, and cite these dangers in order to show that simple extraction does not always prove, in the hands of others, the same simple and safe operation that recent eminent authority has claimed it to be; and that the recommendation of Professor Schweigger that it supersede the operation of Graefe is not, in the present state of our experience, to be unreservedly accepted.

May not the operation, however, be restricted to certain cases, and are not certain special rules to govern the after-treatment? The writer has laid down the following principles for his own guidance:

(1) He would reserve simple extraction for those cases in which the cataract is ripe, the nucleus large, the patient tranquil and amenable to discipline.

(2) After the operation, the application of the bandage should be slightly delayed, the object being to ascertain whether the iris, once replaced, shows any tendency to again prolapse. If it does so, it is to be at once excised.

(3) Eserine is to be applied directly to the eye immediately after the operation, and dropped in the inner corner of the eye, without separating the lids (as recommended by Schweigger) for the three following days.

(4) Greater quiet on the part of the patient is to be insisted on than has been the case after the operation of Graefe.

(5) The eye needs to be inspected much sooner, certainly by the end of the third day.

And even if these or similar rules be followed, I cannot resist the belief that for the average surgeon, and in the present state of our knowledge, simple extraction at the best involves an element of danger that is wanting in the method of Graefe. The successful extraction without iridectomy is unquestionably the more brilliant of the two methods, and the patient thus cured a more striking exemplification of surgical skill. A greater familiarity with the new operation may cause the risk to assume inconsiderable proportions. But some risk is likely to always remain. It is like the old question as to the relative advantages of ether and chloroform: the latter easier to transport, pleasanter to take, quicker in its effect, and occasionally, alarming in its consequences.

A CASE OF ACUTE DIFFUSE NEPHRITIS; URÆMIC CONVULSIONS; RECOVERY.¹

BY HAMILTON OSGOOD, M.D.

On the 4th of January, 1887, I was called at 11 P. M. to a young lady (aged twenty-five, single, heretofore in excellent health), whom I found in constantly recurring epileptiform convulsions, the seizures reappearing nearly every twenty minutes.

I learned that the patient had been slightly ailing for a few days, during which she had been in the hands of a homœopath, then present. The only symptom of moment had been a moderate œdema, chiefly of the face, and which had entirely disappeared before I was called. This symptom the attending physician had pronounced a combination of erysipelas and muscular rheumatism, and had not at any time examined the patient's urine.

At 12.30, noon, of the day on which I was called, the convulsions appeared suddenly, without warning, and up to the hour of my visit no form of relief had been attempted. Invaluable time had been lost, and the case had reached a condition of great danger. Shortly after my arrival the homœopath was dismissed.

To recapitulate: On January 4, 1887, a female, aged twenty-five, unmarried, heretofore in good health, was suddenly seized by convulsions of extremely violent character, recurring nearly every twenty minutes, and having existed *eleven* hours before I was called, nothing having been done to arrest them. The pulse was uncountable; heart in tumultuous

¹Read before the Boston Society for Medical Improvement, Monday Evening, January 23, 1888.

⁹ Kl. Monatsblätter, 1887, Heft 4, p. 105.

action and threatened with paralysis; respirations irregular, temperature 104° ; face livid; tongue and lips badly bitten and swelled; anuria nearly absolute; skin dry and rough. During the intervals between the convulsions the patient was totally insensible, and coma was imminent. The eyes were brilliant and staring, the head turned incessantly and with great rapidity from side to side with a spasmodic movement, and there were decided indications of nausea.

These symptoms, together with a history of oedema, now disappeared, made probable the diagnosis of acute nephritis with uræmic intoxication. The only symptoms preceding the convulsions had been the oedema six days, and a headache twelve hours previously. So far as could be learned by a subsequent careful search into the history of the case, the only causes had been great physical exhaustion and exposure to a current of cold air in a very warm chapel at a Christmas festival, followed by a moderate chill. The small amount of urine which was voided was passed involuntarily. I at once, however, was able with my catheter to obtain about half an ounce. An immediate test converted it into an almost solid, gelatinous mass.

The nurse was now directed to sponge the patient with hot vinegar (for it did not seem wise to put her into a hot bath), and then wrap her, nude, closely in a hot blanket, and cover with as many other blankets as were at hand. Ether was then administered. At the first inhalation, the patient was seized with the most violent convulsion which she had yet experienced. After its cessation ether was again applied, with success. Two light convulsions followed, the last and final one occurring at 1:30 A. M., on the 5th. The anæsthetic was administered three times.

By this time sweating had become very profuse, and was continued three hours. One-eighth of a grain of elaterium was then given, and repeated every two hours until eight pills had been taken. The impossibility of making the patient swallow was overcome by causing the fresh pills, as they were given, to adhere to the teeth. Thus they were not ejected, but, dissolving quickly, were swallowed, and soon created abundant watery dejections.

So soon as the patient would swallow automatically, the administration of a strong infusion of juniper berries containing one ounce of potassic bitartrate to the quart was begun, two pints being taken during the following twenty-four hours.

January 5th. After the unruly night just described the patient was still unconscious. Temperature nearly normal; pulse irregular, but in the vicinity of 100; urine strongly acid, very albuminous; specific gravity, 1036. The microscope revealed white and red blood-corpuscles, the latter largely predominating; abundance of renal epithelium, round cells, hyaline and granular tube-casts, etc. Treatment continued, patient being kept in a state of mild transpiration.

January 6th. During the previous night patient had been very restless, but without convulsive attacks. She was now sensible, but bewildered, and for a fortnight afterwards could not recall the week preceding my first visit, nor could she remember that a homœopathic had been in attendance. Urine had increased to six ounces in the twenty-four hours, the albumen rapidly lessening in amount. The infusion of juniper and potash was continued. The heart still being over-active, the tincture of digitalis was ordered in doses

of ten drops every six hours. Elaterium was renewed for the second and last time in doses of one-twelfth of a grain every two hours, twelve pills being taken with satisfactory results. Diet liquid, principally milk; the juice of one orange in twenty-four hours.

January 7th. Patient brighter. Mind clear as to present events. Pulse 96 to 102, and this count remained unchanged until the 13th. Temperature normal. Quantity of urine had increased to twenty-four ounces in the twenty-four hours. Amount of albumen decidedly diminished. Patient sleeping more quietly. Continued the infusion, and increased the tincture of digitalis to twelve drops, four times daily. Ordered Apollinaris water as a beverage. Added various meat-broths to the diet.

January 8th to 10th. The same general history of steady improvement. Albumen disappearing and urine increasing in daily quantity. Temperature, normal. Began the administration of one teaspoonful daily of comp. licorice powder which secured two loose dejections.

January 11th. One week after the cessation of convulsions. A comfortable day; treatment unchanged.

January 12th. Albumen only a trace. Pulse in the nineties. Temperature normal.

January 13th. Patient seems well. Specific gravity of urine 1024. Quantity between twenty-four and thirty-two ounces. Albumen, a cloudy trace.

January 14th, 15th. Steady improvement. Pulse 88, respiration 18, temperature normal. Urine forty ounces. Specific gravity 1018. Slight trace of albumen. Omitted the digitalis, and lessened quantity of licorice powder.

January 16th. Pulse 84, temperature normal. Tongue clean but intensely red. Circulation sluggish. Some pain in calves of legs. Bowels, three dejections. Specific gravity of urine 1014. Quantity forty ounces. Albumen, a cloudy trace by Heller's first method. Sponging with hot vinegar had been continued twice daily. Renewed the digitalis.

January 17th. Pulse 84, temperature normal, respiration 18. Tongue clean and less red. Specific gravity of urine 1010. Quantity in twenty-four hours fifty-six ounces. Not a trace of albumen either by Heller's first method or by picric acid. Bowels, three dejections.

January 18th. Specific gravity of urine 1010. Quantity fifty-four ounces. No albumen. Reduced the quantity of infusion, one pint of which had thus far been taken daily.

January 20th. Specific gravity of urine 1018. Quantity thirty-two ounces. No casts, blood-corpuscles, nor albumen.

January 21st. Tenderness on pressure over abdomen. Ordered spice poultice; stopped licorice powder for one day. Specific gravity of urine 1014. Quantity thirty-two ounces. No albumen.

January 22d, 23d. Abdominal tenderness gone. Patient exchanged bed for easy-chair for first time. Further details are unnecessary. With the exception of the merest trace of albumen, the symptoms of nephritis actually disappeared seven days after my first visit, following which, careful examinations of the urine made during the next four weeks, and semi-monthly during the succeeding month revealed no trace of albumen nor of any other sign of renal disturbance. Since that time the patient has avoided

undue fatigue, has faithfully protected herself from chill, and to-day is in excellent health.

Acute nephritis is not a rare disease and is especially apt to appear in epidemics of scarlet fever and diphtheria, particularly in children. According to Eichhorst,² Rosenstein,³ Strümpell,⁴ Bartels,⁵ Tanner,⁶ Da Costa,⁷ Vogel⁸ and other writers, climatic changes, over-indulgence in alcohol, chill, heavy falls upon the back, poisonous effects of acrid diuretics, of carbolic and salicylic acids, potassic chlorate, mineral acids, may all cause acute nephritis. It follows infectious diseases and not infrequently appears in connection with syphilis, pulmonary consumption and malaria. It is a sequel of affections of the blood and is caused and favored by cardiac ailments. It sometimes appears as a very serious complication of pregnancy.

Traube⁹ reports a case in which it appeared as a complication of pleuro-pneumonia. According to Bartels¹⁰ the cause of its most dangerous form is undoubtedly scarlatina. Frequently the cause is completely obscure.

Of somewhat curious interest is the multiplicity of names which have been applied to this disease. Freichs called it: "The first stage of Bright's disease." Unusual abundance of white corpuscles in the urine led certain writers to describe the affection as "catarrhal nephritis." Other authors, notably Niemeyer,¹¹ because of the quantity of fibrous cylinders in the urine of some of their cases, applied the name "croupous nephritis." Johnson, of England, was the first to use the expression "desquamative nephritis," as best fitted because of the numerous epithelial cells cast off by the urinary tubules. "Epithelioid nephritis" has been the resource of other writers. "Acute tubal nephritis" is a term applied by Dickinson. Traube is responsible for the name of "hemorrhagic nephritis," for obvious reasons which naturally do not hold good in every case.

Strümpell¹² mentions a variety of this disease which he considers rather characteristic and which has been described by Klebs, Friedländer and Ribbert, under the name of "glomerulo-nephritis," and in which the renal changes are found chiefly in the glomeruli, the same condition being denoted by Traube¹³ as "capsulitis." Bartels¹⁴ prefers "acute parenchymatous nephritis," which, as Eichhorst¹⁵ remarks, does not answer, because the renal anatomical changes by no means confine themselves to the epithelial investiture of the tubules, and he adds, wisely it seems to me, that since nearly all the various terms applied to this disease are descriptive merely of irregular and almost accidental results of the inflammation, the name which best expresses the general pathological condition of the kidney in this affection is, "acute diffuse nephritis," all other terms being subordinate.

PATHOLOGY.

The effect upon the kidney of this form of nephritis is not less varied than the nomenclature. Sometimes the renal organs are found macroscopically perfectly intact, far-reaching anatomical changes being discov-

erable only by means of the microscope. When the kidneys are visibly changed in structure they generally assume one of two forms, namely, that of the acute inflammatory hyperemic kidney or that of the acute inflammatory white kidney. In the one the organ is usually much enlarged, even to double its normal size. The capsule is tensely stretched, springs back under the knife, and probably releases oedematous fluid. The surface of the kidney should be much congested and clearly show distended venous stars. The cut surface still better exhibits the hyperæmia. The cortex has a bluish or very dark red color, making a good background for distinctly visible malpighian tufts, which, as red points, make their surface uneven to the finger or to the eye by refracted light. The medullary substance is still more intensely injected. Almost constantly there are minute hemorrhagic spots which are especially confined to the cortex. In consistence this species of kidney is friable.

The white kidney, the other form frequently created by this disease, is also enlarged, but differs from the other variety in being yellowish-white in hue, the cut surface of the cortex having an especially cloudy look. Fatty degeneration is indicated by yellowish spots and stripes. Scattered hemorrhagic flecks are generally observed on the exterior as well as upon the cut surface of the organ, though they sometimes are wholly absent. Writers on renal disease think this probably secondary to the more active hyperemic condition. Eichhorst,¹⁶ however, says he has found the white kidney in very acute cases and quotes one, fatal in eight days, in which Klebs found the white kidney; but Eichhorst admits that stages intermediary to the hyperemic and the white kidney sometimes exist.

The urinary tract may show evidences of inflammation. Oedema of the skin and fluid in the serous cavities are frequently found; dilatation and hypertrophy of the heart have lately been observed by Friedländer after scarlet fever; by Leyden after typhoid fever, both being complicated by acute nephritis, and by Eichhorst in a case of so-called rheumatic nephritis.

Various writers hotly dispute the indications of microscopic evidence in the affection in question. Some declaring the malpighian corpuscles to be the seat of origin of the disease; others that the epithelium of the cortical tubules is first affected; still others, that interstitial inflammatory changes are the cause.

The malpighian corpuscles are said to be particularly obnoxious to scarlet fever. The epithelium of the cortical tubules, it is claimed, are the common centre of inflammation following diphtheria. In many cases circulatory changes create, very early in the disease, a disturbance in and finally fatty degeneration of, the epithelium of the loops of Henle thus giving warrant to Bartels'¹⁷ term of acute parenchymatous nephritis.

The various names given to this disease are thus explained.

The bloodvessels are frequently found in a changed condition, either widened by hyperæmia or compressed by oedema, and evidence of hemorrhage is common in the interstitial tissue, partly in the urinary tubules, and even in the corpuscles of malpighi.

The epithelium cells may show a cloudy swelling after infectious diseases, fatty degeneration following acute infection and poisoning by phosphorus. Ne-

crisis is a sequel of toxic irritation. Countless hyaline and granular, perhaps blood casts, are found in both straight and looped tubules of the kidney; likewise cellular exudation, white and red blood corpuscles, blood pigment, necrotic and fatty epithelial cells, etc. These evidences are of great value especially in those cases in which the microscopic testimony is at fault.

This rude outline of the pathological changes in this affection is all that seems admissible in the hasty report of a single case with the exception of the farther statement of Axel Key, in connection with cases which end in recovery, that under increasing fatty degeneration of the epithelial cells, also to a certain extent in the same process in the round cells of the interstitial stroma, resorption occurs, necrotic and fatty cells are carried away by the urinary current and regeneration of the epithelium is effected by emigrated white blood corpuscles, according to Strümpell, from the epithelial cells which still remain.

Of the symptoms of acute nephritis enough has already been said to make it seem needless to add other details.

DIAGNOSIS.

The diagnosis of acute nephritis in average cases is not difficult. The cause is a helpful assistance, but the quality of the urine is generally characteristic, being more or less bloody, of high specific gravity, very acid, small in quantity, containing much albumen, the sediment being rich in blood corpuscles, cylinders, in a variety of tubal epithelium, etc.

Traumatic hæmorrhage of the kidney would be made apparent by the history and the small amount of albumen in the urine.

Embolic hæmorrhage would be explained by suddenness of onset, pain, chill and vomiting, together with a concurrent valvular lesion of the heart.

Venous hyperæmia of the kidney is excluded by the great predominance of the characteristics of the urine already cited and by the fact that hyperæmia is usually associated with lesions of the heart or respiratory organs.

It is often difficult to decide between an idiopathic acute nephritis and an acute exacerbation in chronic nephritis. The course here would be the attempt to discover whether symptoms of a renal affection have existed long before the present attack. In some cases it would be useful to leave the diagnosis open in order to give time for acute symptoms, especially hæmaturia, to cease.

After making the diagnosis of acute nephritis certain, Eichhorn¹⁴ lays great emphasis on the necessity of discovering the cause, since upon it the treatment to be adopted may depend, as for example, in syphilis or malaria.¹⁵

PROGNOSIS.

The prognosis in many cases naturally depends not only upon the degree of the renal affection, but also upon its primary cause.

Bartels¹⁶ says that in complete suppression of the urine the prognosis is absolutely bad, he never having seen such a case recover. Eichhorn¹⁶ asserts that an especially unfavorable prognosis is to be pro-

nounced when the quantity of urine is small and uræmic symptoms appear.

Vogel¹⁷ expresses the opinion that the appearance of uræmic symptoms is serious and often quickly cause death. Tanner¹⁷ thinks the prognosis may be favorable, the chief points to be feared being the occurrence of uræmia and diminution of the urine. Traube¹⁷ reports a fatal case in which death occurred during coma, no convulsions having appeared; and makes the interesting *post-mortem* statement that oedema of the brain, as in this case, may exist without convulsions. Da Costa¹⁷ states that uræmic intoxication is invariably followed by death unless the urinary secretion be freely re-established. Flint¹⁸ says that coma and convulsions denote imminent and great danger to life, but that recovery sometimes occurs notwithstanding these effects of uræmia.

Strümpell¹⁹ thinks the prognosis in many cases, in addition to the renal affection itself, depends, first, much upon the primary cause, especially if this be another disease; second, upon the uræmia, especially in the severe convulsive form with high temperature and concurrent paralysis of the heart; and third, upon the inflammation of internal organs in which secondary pneumonia is not a rare cause of death, while secondary pericarditis and peritonitis are observed only in isolated cases.

Eight to fourteen days is the average duration of the disease after which time appears recovery, death or chronic nephritis.

Of treatment, it seems necessary to say only that the course or one similar to that which was successful in the case in question, would probably answer in all cases in which there were no coincident ailments, especially syphilis, malaria or poisoning. These would suggest their own specifics.²⁰

ON THE USE OF LANOLIN AND BORACIC ACID IN CERTAIN DISEASES OF THE SKIN IN CHILDREN.¹

BY RUSSELL STURGIS, M.D.

I wish, this evening, to call attention to the use of an agent with which I have been much pleased, and hope that I can induce those who have more opportunities of treating the skin than I to give it a more extended trial. I have used lanolin (with which arginine, manufactured by T. Metcalf, plus fifty per cent. water is said to be identical), in the Children's Room at the Boston Dispensary during last winter and this. Those cases in which I have found it of use are facial eczema and eczema of the head, eczema squamosum, eczema rubrum and intertrigo, the mild form of seborrhœa often seen on the temples and about the chin, and lastly, chronic urticaria.

In eczema of the face and head, where there is on the face a more or less raw surface from scratching, with papules, vesicles, and pustules, and, on the head, a similar condition of things existing under a dry, dirty, yellow crust; I first direct that the head and face shall be cleaned of the crust in the usual

¹ Read before the Boston Society for Medical Improvement, January 23, 1888.

¹⁴ Loc. cit.

¹⁵ Pract. of Med.

¹⁶ Loc. cit.

¹⁷ The writer purposely refrained from the use, in the case reported, of pilocarpine, because of already existing nausea which he did not care to take the risk of increasing in a case of such gravity.

¹⁸ Loc. cit.

¹⁹ In an attempt to decide between acute and chronic nephritis hypertrophy of the left cardiac ventricle, as suggested by Dr. F. C. Shattuck during the discussion upon this paper, would be useful as signifying the probable existence of the chronic form of nephritis.

²⁰ Lehrbuch der Spec. Path. u. Ther.

way. Should the exposed surface be weeping copiously, I prescribe boracic acid in very fine powder, to be dusted on for the first forty-eight hours, night and morning, and not to be washed off.

The first effect of the acid is generally to increase considerably the serous flow, but, after twenty-four hours, to diminish it. After forty-eight hours I direct that the boracic acid, as much as may be left mixed with the dried serum, shall be washed off with warm water. The surface is now seen to be less inflamed, and not discharging as much as when the crusts were first washed away. I now direct that the boracic acid shall be applied night and morning, washing off each time the acid applied the time before. As soon as the skin is in condition to bear an ointment, I use one of boracic acid, $\mathfrak{z}\text{ii}$, to lanolin, $\mathfrak{z}\text{i}$, by which the acid is kept in contact with the skin better than if used in powder.

Boracic acid alone or with lanolin acts in a very satisfactory manner in alleviating the intense itching of eczema: much less restraint being necessary to prevent the child from damaging the skin by scratching. In cases where the eczematous patch is so situated that it is not rubbed by the bed-clothing, as on the vertex and anterior aspect of the cheeks, I prefer to use no covering, because there is not so much danger of tearing away the crusts that may form and become adherent to such covering. Agnine, being rather stiff, constitutes a covering itself which is not easily removed. When the patch is on the neck or about the ears, I use absorbent cotton kept in place by a bandage or cap. Unruptured vesicles and pustules near the margin of a patch I slit myself, reducing them to the same condition as the unprotected skin in the centre of the patch.

In eczema of the face, after most of the redness and evidence of acute inflammation have subsided, I treat the induration which is left by dailyunction, morning and night, with pure agnine. My directions are to rub on enough to give the skin a brown color; then rub this in till the surface scarcely feels greasy, and until the brown color is replaced by light yellow, or has disappeared. If the rubbing is as vigorous as directed, the induration soon disappears. I do not know whether the lanolin is the beneficial factor, or whether it is the massage with lanolin as the emollient.

In cases of eczema squamosum in which there is considerable induration, with scaly surface, accompanied by cracks or not, I first clean off the scales with plenty of hard rubbing with sweet oil, and washing with castile soap. If one scrubbing is not enough to clean the patch, I keep on till it is clean. Then, night and morning, I direct brisk, hard rubbing with an ointment of 5-15 grains of salicylic acid to the ounce of lanolin, according to the degree of induration. This treatment will, I think, restore the skin to its normal condition in less time, and with less discomfort to the child than the more painful application of oil of cade and the stronger alkalis. The advantage is, that when lanolin is used I have not been compelled to use this harsher treatment. I have not been obliged to use any stronger irritant than fifteen grains of salicylic acid to the ounce to get the effect that I wanted. My impression is that this is due to the fact that probably an irritant is brought into closer contact with the deeper layers of the skin by the means of lanolin, than if it were applied more to the surface, without lanolin being used. In this con-

nection, it may be mentioned that in infants and young children, with their delicate skins, induration and scaling probably yield to much milder remedies than the tough, old cases in adults, in which strong irritants are called for.

In cases similar in appearance to eczema squamosum, but which are really seborrhoea, which I have mentioned before as common on the faces of children, where there is no induration, and little or no change in color of the surface, an ointment of five grains of salicylic acid to the ounce of lanolin, used night and morning, is enough to remove the scales. After the disappearance of the scales, I use lanolin alone once a week or oftener to keep the skin in good condition, as such scaly patches are prone to return, particularly in winter.

In chronic urticaria, I am inclined to think that we have in lanolin a reliable application to alleviate the itching, which is usually so difficult to control. I have had the opportunity of using it in three cases only. In a case which I hoped to show here to-night, the urticaria had lasted for three weeks before the child came to my room, on January 7th. I directed the mother to use lanolin on the right side only, leaving the back and left side alone. I gave no internal treatment, as the general health of the girl was perfect, nor could I learn of any article of food that was likely to cause the trouble in her case. I saw her again on the 11th. Her mother reported that since the application of lanolin there had been no itching of the side treated, the other side had itched as much as before, particularly in the evening, and welts made their appearance, as usual. I directed the ointment used as before, on the right side only, which now was much improved in appearance. On January 14th all signs of scratching had disappeared from the right side, and the left looked better and felt somewhat greasy. I taxed the mother with using the ointment on the left side: she denied it. January 18th, I saw the child only; she reported all the itching, back and front, to have gone, and owned up to using the lanolin otherwise than as directed. I had hoped to be able to show this case with symptoms of urticaria on one side, with a well-marked line of demarcation between the sound and affected side.

In regard to the antiseptic properties of lanolin, Dr. Gottstein, in an article which appeared in the *Berliner Klinische Wochenschrift*, November 28, 1887, and which is reviewed in the *British Medical Journal* of December 21, 1887, states that lanolin is absolutely inimical to the growth of micro-organisms, of whatever kind they may be. In this connection, it may be mentioned that Liebreich has shown that cholesteroline fats, which are chemically the same as lanolin, are a normal constituent of the epidermis in man and the lower animals, thus constituting the most powerful protection against infection from without. In the employment of lanolin, therefore, we are using not only a superior emollient, but also are saturating the skin with a substance upon and in which it is impossible for micro-organisms to exist.

I had occasion to use boracic acid first some three years ago, in a case of often recurring eczema behind the ears, which had resisted most successfully other modes of treatment. The case did so nicely that I have since used it whenever I have had occasion to treat eczema rubrum and intertrigo in children. I direct that the pure, finely-powdered acid shall be

dusted over the parts night and morning, and, when about the genitals, whenever the napkins are changed. Each night and morning, the acid previously applied should be removed before more is put on. Since employing this treatment I have had no occasion to use zinc and starch powder or zinc ointment, which I used before as routine treatment. When now their use is indicated I use pure boracic acid, or boracic acid with lanolin.

In regard to internal treatment, I am guided wholly by the general condition of the case, regarding the skin disease in eczema as entirely local. In conclusion, I would say that I have found, in general, boracic acid of value where there is much serous oozing; boracic acid and lanolin where there is less; lanolin alone where there is moderate scaling and induration, and in urticaria; salicylic acid and lanolin where there is considerable scaling and induration.

REPORT ON OBSTETRICS.

BY CHARLES M. GREEN, M.D.

THE CONTRACTIONS OF THE UTERUS THROUGHOUT PREGNANCY, AND THEIR VALUE IN THE DIAGNOSIS OF PREGNANCY, BOTH NORMAL AND COMPLICATED.

BRAXTON HICKS (London) contributed a paper on this subject to the Obstetric Section of the recent International Congress in Washington. In the fifteen years since he had first directed attention to this phenomenon, the diagnostic value of these contractions had been amply demonstrated. He pointed out that before the fourth month the contractions could not be detected without bimanual palpation, but after that time they could be appreciated by external palpation alone. The deductions¹ from his paper were:

"1. That the uterus contracted at intervals of from five to twenty minutes during the whole of pregnancy, remaining contracted for from three to five minutes.

"2. The uterus is firm when contracted, and the fetus cannot be distinctly felt, though when the uterus is soft the fetus is easily mapped out.

"3. By noticing the contractions we are often enabled to diagnose normal pregnancy from other conditions.

"4. The contractions have the physiological use of emptying the uterine veins of the carbonized blood.

"5. The carbonized blood probably excites the contractions."

POSTURAL TREATMENT IN DYSTOCIA FROM SHORT OR COILED FUNIS.

KING² (Washington) again calls attention to the postural treatment of dystocia due to short funis, whether the cord is absolutely shortened or simply coiled round the fetal neck, the conditions being the same in either case. He was led to suggest this method of treatment by noticing in three cases of this condition "a persistent desire on the part of the patient to assume a sitting posture." Of course with the patient on her side the fetus must in a certain degree be forced by the uterine contractions *upwards*, the fundus lying on a lower plane than the pelvic

outlet, and at the same time the parturient canal is to some extent lengthened with the patient in a latero-prone position. On the other hand, with the patient in a sitting, squatting or kneeling posture, gravity forces the uterus and its contents deep into the pelvis and shortens to some extent the parturient canal, and thereby in many cases (without extreme shortening of the cord) a sufficient space is gained to enable the head to be born, or to come low enough to admit of the easy reaching and cutting of the cord if it cannot be uncoiled. The suggested method is a reasonable one, and worthy of remembrance and trial.

THE VALUE OF THE GENU-PECTORAL POSITION IN DIFFICULT VERSION.

CUTTS³ (Washington) recalls attention to the value of the knee-chest posture in certain cases of version, this position having been originally suggested by Deventer, recommended by Snellie, and among Americans by Bard, Shippen and Maxson, the latter showing its advantages in cephalic version. Of course the object of the position is chiefly to take advantage of the force of gravity to assist in the disengagement of the presenting part. As stated by Cutts, quoting largely from other writers, the advantages of the posture are:

"1. The downward pressure of the atmosphere upon the fundus uteri is, at least in part, equalized by the admission of air into the vagina.

"2. We have the force of gravity to aid us. The weight of the child naturally drags the presenting part from the os uteri and pelvic cavity, and by so much relieves the impaction.

"3. The abdominal cavity is elongated, putting the vagina upon the stretch, thereby giving it a cylindrical character, thus aiding to throw the head into line with the superior strait.

"4. The woman cannot, in this position, to any extent exert her voluntary muscles in bearing down.

"5. The uterus with its contents recedes from the spine and by force of gravity tends to relax the abdominal muscles and hence favors our manipulations.

"6. It is more than probable that in this position the uterus will be found physiologically to contract less violently and relax more readily than when the patient is on the back or side."

The great difficulty of this posture is in keeping the patient in position when she is etherized, and several assistants would always be necessary: for cephalic version, however, an anæsthetic might generally be dispensed with. If for any reason this posture is inadvisable, many of its advantages may be attained by a considerable elevation of the hips. [As suggested by Cutts and others, this expedient is worthy of trial in those cases of occipito-posterior position with the head above the superior strait, where engagement fails to take place owing to disproportion between the biparietal diameter and the sacro-iliac arch. In such cases, gravity, assisted perhaps by external manipulations, would often bring the fetus to an anterior position.]

"NORMAL FORCES."

LAZAREWITCH⁴ (St. Petersburg) has devised a new forceps having parallel blades and without pelvic curve. The cephalic curve is less than usual, and is

¹ Amer. Jour. of Obstetrics, Oct. 1887, p. 1068.

² Jour. Amer. Med. Assn., Sept. 24, 1887.

³ Amer. Jour. Obstet., Nov. 1887.

⁴ Centralblatt für Gynäk., No. 28, 1887.

swept on a 20 cm. radius; when applied the forceps is locked by a sort of bolt passing through oval openings in the handles and fastened with a screw. The inventor claims as the advantages of these modifications,—greater ease of application and use, and a diminished risk of injury to the maternal soft parts and to the foetal head. The critic in the *Centralblatt* says that this instrument is only a modified reproduction of Chamberlen's original forceps, and therefore a step backward.

Professor Lazarewitsch exhibited his forceps at the Washington Congress⁸ last September and described in detail the advantages he believed his instrument to possess. It is certainly courteous to abstain from adverse criticism until the forceps has been fairly tried, even though it may seem probable that the instrument is in no way superior to any straight forceps of equal length and strength. [It is a matter of local interest that Professor Lazarewitsch presented the forceps he had exhibited in Washington to the Obstetrical Society of Boston, and that Society will doubtless hereafter publish by Committee the results of an extended trial of the instrument.]

DEVENTER'S METHOD OF DELIVERING THE AFTER-COMING HEAD.

BARTLETT (Chicago) has brought this old method to modern attention in a paper⁹ read at the recent Congress. Deventer's method, which was mentioned with approval by Smellie, differs radically from the Prague and Smellie-Veit methods, in that in the former the child's body is carried back against the perineum, so that the anterior surface of the neck rests against it, while the occiput is turned out from under the pubes. The arms are not to be drawn down, but left on each side of the head, thereby protecting the neck and funis from pressure. The method is only applicable to cases with occiput anterior, and backward traction is to be supplemented by supra-pubic pressure. [It would seem that by this method the perineum must inevitably be badly lacerated: it is stated, however, by those who have tried it that such is not the case. Certainly the method is worthy of careful trial.]

HYPNOTIC ANALGESIA DURING LABOR.

DUMONTALLIER⁷ hypnotized a young woman during labor whom he had already proved during her pregnancy to be an easy subject: he brought her into a condition of somnambulism. During this state she felt the uterine contractions, but suffered no painful sensations, so that after each awakening from her trance she begged to be again hypnotized. With increasing strength of pains, however, the uterine analgesia ceased, and finally it was no longer possible to bring her into the hypnotic state.

According to an observation of Pritzl (Vienna), women in labor, if brought into the hypnotized condition, are said to feel no pain even to the end of their labor: and the pains are said to decrease neither in force nor frequency.

THE VALUE OF COCAINE IN OBSTETRICS.

MR. JOHN PHILLIPS has published in the *Lancet* for November 26, 1887, an analysis of the more im-

portant contributions to this subject, and has considered the action of the drug under five heads:⁸

1. *The Vomiting of Pregnancy.*—Cocaine has been used for this affection by many observers: the experience of WEISS and of BOIS has been previously noticed in these Reports,—the former giving the drug by mouth every half-hour in $\frac{1}{16}$ grain doses in solution, the latter using a two per cent. admixture with vaseline and placing a tampon smeared therewith against the cervix morning and evening. FRAIPONT has reported several successful cases, and has employed the drug by subcutaneous injection (20 minims of a four per cent. solution) into the epigastrium. ENGELMANN reports an obstinate case in which he was successful in two days, giving thrice daily by mouth ten minim doses of a ten per cent. solution. PHILLIPS has used the drug in two cases,—once with marked success: in his second case it was uncertain whether the cessation of vomiting could be fairly attributed to the use of cocaine.

2. *During the First Stage of Labor.*—Here it is reasonable that cocaine should alleviate the pain resulting from the stretching of the nerves of the cervix and from the more or less laceration of cervical tissue. DOLEIS and DEBOIS experimented with eight cases, with a favorable result in six: they painted the cervix through a speculum with a four per cent. solution of hydrochlorate of cocaine in glycerine. JAENNEL applied cotton tampons soaked in a five per cent. solution to the cervix and posterior cul-de-sac, and was successful in three out of five cases: he cautions against the use of corrosive sublimate donches after the application of cocaine, as he found that the sublimate rapidly decomposed the alkaloid. FISCHER was successful in three cases with a two per cent. solution applied to the cervix on a tampon; but in two other cases a similar application of a four per cent. solution gave a negative result. PHILLIPS disbelieves in the use of a speculum for several reasons and prefers to administer the drug by suppository: he was successful by this method in three out of four cases.

3. *During the Expulsive Stage of Labor.*—From the complex nature of the pain of this stage, any certain or marked relief by cocaine is out of the question. PHILLIPS tried the drug in six cases, either by inserting a saturated tampon (five per cent. solution), or by painting the vulva, with practically no amelioration of pain. FRANKEL concludes an elaborate paper on this subject as follows: "It is little probable that cocaine can be used as a local anæsthetic in labor, because anæsthesia and analgesia developed under this drug are essentially superficial, while the pains of labor are the result of distension and stretching of the tissues through their whole thickness."

4. *In Obstetric Operations.*—It has been suggested that cocaine may be useful in hyperæsthetic patients to anæsthetize the vulva prior to the introduction of a catheter for inducing premature labor, for the application of short forceps, for removing an adherent placenta, or for passing the catheter in a recently delivered patient. But while possibly of occasional value, it is obvious that the use of cocaine must have a very limited application.

5. *In sore nipples.*—In this condition cocaine has been frequently tried, but with doubtful results. HERGOTT used a four per cent. solution in nine cases

⁸ See Report in *Amer. Jour. Obstet.*, Oct., 1887.

⁷ Abstract in *Amer. Jour. Obstet.*, Oct., 1887, p. 1082.

⁹ *Journal d'Accouch.*, 1887, No. 6.

Centralblatt für Gynäkol., 1887, No. 13.

⁸ *Therapeutic Gazette*, January 16, 1888.

and found that the mother could then suckle without pain, that cauterization of the nipple with nitrate of silver was painless, and that the fissures rapidly healed. PHILLIPS tried a six per cent. solution in four cases, and was disappointed with the result: the anaesthesia produced was more or less deep, but lasted only two minutes, and the fissures did not tend to heal more quickly. He found that infants did not hesitate to take the nipple after the application of the drug, and that they were not injuriously affected thereby.

The following conclusions may be drawn from Mr. Phillips's paper: "1. That cocaine in whatever way administered for uncontrollable pregnancy vomiting, is a valuable adjunct, and in some cases a superior drug to those at present in vogue. 2. That during the painful earlier stages of labor, especially in primiparae, it materially assuages the pains, but neither quickens them nor retards their onset, and hence has no effect on the actual dilatation. 3. That it is useless in mitigating the pains of expulsion, and those caused by pressure on the primum. 4. That in the case of sore nipples it relieves the pain attendant on suckling, though the duration of its effects is not sufficiently long to be of material service. It is, however, without any apparent detrimental effect upon the suckling."

RUPTURE OF THE FUNIS FROM SUDDEN EXPULSION OF THE CHILD WITH THE MOTHER IN HORIZONTAL POSITION.

That the funis may tear, if the child is suddenly born with the mother in a standing or kneeling position, is a well-known fact; but that this accident could happen with the woman lying down would appear very doubtful. Such cases have been reported by Nargoll, Späth, and others, in which rupture occurred owing to undue shortness of the funis; but hitherto only two cases have been reported of rupture of a cord of normal length, — one by Späth (fetus macerated) and one by Dupuy. To these BÉGIN⁹ (Paris) adds two cases. In both cases (one a *ii*-para, one a *i*-para) the forcible and sudden expulsion of the child resulted in a rupture of the funis, — in one about 3 inches, in the other about 4 inches, from the naval of the child. In the case of the *ii*-para the torn cord bled freely from both ends; but in the other case the funic haemorrhage was very slight.

[Such cases are of great medico-legal importance, but we fear their citation may sometimes embarrass the administration of justice in certain cases of suspected infanticide, in which the plea in defence is: precipitate labor unattended, with rupture of the funis and consequent fetal death.]

Clinical Memorandum.

A CASE OF SARCOMA OF THE TONSIL REMOVED BY EXTERNAL INCISION. RECOVERY.

BY M. H. RICHARDSON, M.D.,
Surgeon to the Massachusetts General and Varying Hospitals, Assistant Professor of Anatomy, Harvard Medical School.

The following case presents several points of interest. The diagnosis was based upon the gross appearances and confirmed by the microscopic examination.

⁹Progres Med., 1887, No. 17. Centralblatt für Gynäköl., 1887, No. 18.

The tumor was removed by a dissection from the outside, and a complete and thus far permanent recovery followed.

Mrs. E. H., aged sixty, came from New Brunswick to the Massachusetts General Hospital, April 9, 1886. She said that she had noticed a swelling back of the angle of the jaw on the left side for two years. It was of slow growth except that it had seemed to increase rather more rapidly for a short time before coming to the Hospital. Externally there was only slight deformity, a small swelling being visible under the left ear. Internally the left tonsil was pushed with the pharynx quite to or beyond the middle line. The appearance of the mucous membrane of the pharynx was normal. The growth was indurated and could be felt under the edge of the jaw from the mastoid process half-way to the chin.

April 13, 1887, the tumor was removed by an incision three inches in length along the anterior border of the sterno-mastoid muscle. A careful dissection was made to get under the parotid behind which the new-growth was found encapsulated. The tumor was lobulated, and had finger-like projections running in various direction. It partly surrounded the styloid process and was attached to it, and from there extended inwards to the middle of the pharynx. It was covered in the throat by the mucous membrane alone. A large portion of the tumor was shelled out, and the rest removed by dissection. The portion projecting into the pharynx was thoroughly removed, leaving nothing but the mucous membrane of the pharynx between the fingers when one was in the pharynx and the other in the wound. The tumor was situated in the place of the left tonsil. It was impossible to say either from the location or the microscopic examination whether the growth started in the tonsil or directly adjacent to it. There was no tonsillar structure discovered by the microscopic examination, or at least none reported. In effect, however, it was a tumor occupying the tonsillar region and interfering with deglutition and respiration. The upward growth of the mass in and between the pterygoid plates, and its attachment to the base of the skull made its complete removal very difficult, and the probability of return very great. After the operation there was a very little venous oozing from the deep parts which was controlled by pressure. The wound was closed with silk and drained. Corrosive sublimate irrigation, and iodoform gauze dressings. During the evening the throat became swollen and ecchymosed on the left side, causing slight dyspnoea. The pressure on the outside was therefore removed. The next day the ecchymosis had extended to the frænum of the tongue and down on the neck. There was paralysis of the left lower lip.

Three days after operation she could eat and talk without trouble. Dressings changed to phenyle pad on account of slight suppuration along track of tube.

April 29th. Throat normal in appearance.

May 5th. Discharged.

November 23, 1887. A letter received from the husband states: "She got quite well in three weeks time, and has not felt any effects of it since, and her health is good." Microscopic examination of the tumor made at the Harvard Medical School was to the effect that it was a round-celled sarcoma.

This case is interesting from its rarity, and from the fact as yet, there is no sign of a return. I was of the

opinion at the time that there would be a speedy reappearance of the disease, and wrote to the husband to ask the date of death, with the above reply. With regard to the feasibility of removing such growths from the tonsillar region it seems to me to be quite a practical operation if the dissection is carried on carefully and there is free respiration. The pharynx not having been opened made it much less difficult than it would have been otherwise.

The question of diagnosis is also interesting. If the tumor involved the tonsil throughout, I do not see how it could have been as thoroughly removed as it was without opening the pharynx. The mucous membrane over the tonsil is so thin that it does not seem possible that the whole gland could have been removed. Yet at the close of the operation there was so thin a partition between the wound and the pharynx that the mucous membrane covering tonsil was translucent.

Reports of Societies.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.

E. M. BUCKINGHAM, M.D., SECRETARY.

JANUARY 9, 1888, the President, Dr. O. F. WADSWORTH in the chair.

Dr. M. H. RICHARDSON read a paper entitled

CASES OF NERVE STRETCHING, NERVE SECTION AND NERVE SUTURE; AND OPERATION TO RELIEVE PRESSURE ON NERVE TRUNKS.¹

Dr. J. C. WARREN said that the subject of nerve section is interesting, because of the wide range that may be given to this mode of treatment. Operations for *tic* are very satisfactory. He referred to a case of trephining for the incision of the inferior dental, reported and illustrated by a picture in the first volume of the *Boston Medical and Surgical Journal* for 1828. He has twice done Wagner's operation on the infraorbital nerve, cutting down on the edge of the orbit, lifting the periosteum of the orbit with a periosteal elevator. With a small spoon bent at an angle, the whole contents of the orbit can be lifted up and the infraorbital canal exposed. The nerve can be separated easily from the artery, drawn out from the foramen and divided from the terminal branches. Laugenbeek used to cut this nerve subcutaneously on the cadaver. Dr. Warren had operated about eighteen months ago, upon the infraorbital (?). The only return of trouble had been some pain at the angle of the jaw, not enough to give serious discomfort. In this case union was by first intention. For stretching the spinal accessory he recommends an incision through the steno-mastoid near its posterior border, rather than Dr. Richardson's incisions.

He had seen one tumor in connection with the musculo-spinal nerve; it had been easily removed, with a good result. He had stretched the nerve for sciatica with good result. It is done easily and without any hemorrhage, through a free incision, and the wound heals readily. He would, however, hesitate to do this in an old subject with chronic sciatica, notwithstanding that old people do well after operation on the face. Nerve-suture has not been looked upon with

favor until lately, but it is now considered a valuable operation.

Dr. G. L. WALTON thought that nerve-stretching will not have such a future as other nerve operations, such as section, removal of tumors, etc. Stretching when done for spasm, has sometimes not relieved it, and has sometimes caused troublesome paralysis. He had seen four cases of sciatic nerve-stretching in Leipzig, done for relief of the gait in locomotor ataxia. This seemed to him a more unreasonable undertaking than stretching on account of pain. Could pain be relieved the speaker thought the result would justify the operation, but the outlook was not promising.

Operations for the removal of cicatrices in which nerves are involved are important. He had seen three within a few months. One case was peculiar. An ice pick had been driven into the thigh and spasms resulted in the calf. This might be called reflex for want of a better name. As a rule, pain caused by a cicatrix is peripheral from the cicatrix. The speaker mentioned a case where a knife had been thrust into the wrist, over the median nerve, causing paralysis of the thumb. Pressure over the median nerve caused tingling in the area supplied by this nerve. Here he had used galvanism every day. Almost complete recovery followed in a few weeks. If, after waiting a month or six weeks, there should be no improvement he would then operate in such a case.

Dr. P. C. KNAPP said that he had been much interested in Dr. Richardson's cases, for they had given him much information in regard to the success and advantages of surgical treatment in a class of cases where medical treatment was often unavailing. He was also glad to hear Dr. Walton condemn nerve-stretching. He had seen it tried in only a few cases, but from the result of these cases and others reported he had felt very doubtful as to the benefits derived from it. Some years ago nerve-stretching was urged as of great benefit in *tabes dorsalis*, but now every neurologist, except Benedict, has abandoned it. He did not consider it a justifiable operation, not only from the lack of benefit derived from it, but from its injurious effects on the spinal cord. In animals whose sciatic nerves had been stretched with the same relative force as in nerve-stretching for therapeutic purposes, it had been found that the stretching produced vacuolization in the motor cells of the anterior cornua, and also more or less sclerosis of the posterior columns, a condition as serious often, as the one which the physician sought to relieve.

JANUARY 23, 1888. The President Dr. O. F. WADSWORTH in the chair.

Dr. RUSSELL STURGIS read a paper on

THE USE OF LANOLIN AND OF BORACIC ACID IN CERTAIN AFFECTIONS OF THE SKIN IN INFANTS AND IN YOUNG CHILDREN.²

Dr. J. C. WHITE asked if the reader had used pure lanolin, or had it been mixed with water.

Dr. STURGIS answered that it was supposed to be pure. If too stiff, from ten to fifteen per cent. of water had been added. The lanolin used had been furnished by the Dispensary.

Dr. WHITE asked if any comparative experiments had been made with lard, and remarked that it

¹ See Journal, No. 6, page 139.

² See page 193 of this number of the Journal.

would be interesting to treat the opposite sides of the same child, one with lard and one with lanolin, the other ingredients of the ointments being the same. In no other way could definite knowledge be got. He had used lanolin to some extent and had not seen any difference in the results as compared with vaseline or cold cream. It has an unpleasant odor, and is occasionally irritating. The experience of one or two of his friends has agreed with his own. He is willing to admit, because of statements made by Liebreich and others, that it penetrates deeper than some other fats, but it does not follow that it has a better effect on eczema. He had had no experience in the use of lanolin alone in the treatment of chronic indurated eczema. He had rarely used boracic acid alone, but had often used it with starch or in ointments, and agreed with the reader that it has value.

DR. STURGIS said, in reply to Dr. White, that in the forty-one cases reported, lanolin had been used during the time mentioned. During the same time lard had been used as an ointment basis in other cases, but had not proved in his hands as satisfactory as lanolin. He also draws attention to the fact that pure lanolin was of little use where there was considerable induration. In those cases it was combined with salicylic acid.

DR. B. F. DAVENPORT said that it is very possible that the varying satisfaction which wool grease has given to those who have just spoken concerning it, may be largely due to the different composition of the commercial varieties which have been dispensed by their druggists. As shown in last July number of the *Pharmaceutische Rundschau*, different samples bought in this city, have been found to contain from 1.25 to 22.12 per cent. of free fatty acids. The preparation of wool grease to which the name of lanolin was originally applied, was one into which a large percentage of water had been worked, just as is the case with the preparation popularly known as cold cream. Another preparation not containing any water is known as agnaine. The large percentage of cholesterine contained in wool grease allows of its taking up a larger proportion of water than any other known commercial form of grease. Samples bought in the city have been found to contain from 0 to 23.74 per cent. of water.

DR. WHITE said that the presence of water is often of material consequence. Experience shows that many skins bear an ointment better if water is mixed with the fat.

DR. HAMILTON OSGOOD read a paper on

A CASE OF ACUTE DIFFUSE NEPHRITIS WITH CONVULSIONS. RECOVERY.²

DR. MINOT said that an interesting feature of the case was its rarity, since acute nephritis was in a large proportion of cases secondary to other diseases, such as the essential fevers, diphtheria, etc., and to pregnancy. He spoke of the favorable effect of pilocarpine injected beneath the skin in alarming cases complicated with stupor, convulsions, and oedema of the lungs, and alluded to two cases in which its administration was quickly followed by the happiest results. One of these was that of a child, two years old, with scarlatina. The other patient was a woman in whom threatening symptoms appeared soon after delivery. In both cases the urine, which previously

contained a large amount of albumen, became normal in the course of a day or two, and the patients recovered perfectly.

DR. GEORGE B. SHATTUCK thought Dr. Osgood's case a very fortunate one, not merely as regards the recovery, but especially as regards its frank response to treatment, and the prompt and steady disappearance of symptoms without relapse or delay. When convulsions and coma present themselves in the course of a nephritis, an anæsthetic is an obvious means of immediate relief, especially if supplementary to the more radical action of some one or more of the rapid eliminative agents. Ether is probably the anæsthetic which would be almost invariably resorted to in this community, on account of its greater reputation for safety. On the other hand, chloroform was probably less irritating to the kidneys, and, in the abstract, better under the circumstances. With regard to the choice between pilocarpine, the hot-air bath, and rapid cathartics, the speaker thought it difficult to lay down positive rules. Individuals varied very greatly in their response to the first two of these agents certainly, and in a less degree to the third. Sometimes pilocarpine was ineffective for elimination, and objectionally active as a depressant, when the hot air-bath was not so, and *vice versa*. There need not ordinarily be any great difficulty about giving the hot air-bath; the wet pack could, of course, always be applied. Digitalis was almost always indicated. He could not consider so-called idiopathic acute nephritis as a very rare disease. Many cases are met with, and he had himself seen an unusually large number this winter, in which no other exciting cause than exposure to cold could be arrived at, and he thought exposure to cold must be accepted as such a cause.

A considerable number of adults had entered the City Hospital this winter with acute nephritis, the result of previous scarlet fever during the late epidemic, the scarlet fever having been unnoticed at the time, or not considered of enough consequence to lay up for. The speaker agreed with Dr. Osgood in deprecating the introduction of new names to describe the disease, or even the retention of most of the old ones — parenchymatous and diffuse nephritis were sufficient.

DR. T. M. ROTCH remarked that he believed that as our knowledge of the symptomatology of infantile renal disease, and the renal disease of young children became more extended, we should find that idiopathic nephritis; that is, a nephritis not incited by the usual recognized causes, as scarlet fever, etc., is not so uncommon a disease as it was formerly supposed to be. He had no doubt that many cases are overlooked, and are considered instances of nutritive disturbance from the absence of certain adult symptoms, notably oedema, and yet where a careful examination of the urine would at once clear away obscurity from the diagnosis, and definitely pronounce the disease to be acute or subacute nephritis.

DR. F. C. SHATTUCK said that the distinction between acute nephritis and an acute exacerbation of a chronic nephritis, a distinction which it may be impossible to make for a time from the urine alone, can usually be made by the presence or absence of notable left ventricular hypertrophy, the nearly constant accompaniment of every chronic nephritis.

In a case recently under observation, this point was relied upon in determining the duration of the disease;

² See page 190 of the Journal.

and it was very interesting, later, to see the enlargement of the left ventricle develop. This patient had repeated uræmic threatenings, which were always as promptly relieved by a vapor-bath, all the requirements of which were met by an alcohol lamp, chair, blankets — and patient.

On his arrival at the Massachusetts Hospital, one morning last summer, the speaker was told by his interne that there was a case of uræmic coma requiring attention. A large man, in the prime of life, was brought into the Hospital the afternoon before entirely unconscious, without any history, and free from œdema. Urine drawn with a catheter was highly albuminous. He was violent during the night, requiring restraint, and toward morning had several severe convulsions, in spite of pilocarpine, a diuretic which started the flow of water, and a purge, all wisely ordered by the interne. When the speaker saw him he was alternately comatose and wildly delirious; the face was much flushed; the respiration stertorous; the arteries hard and bounding. He was bled thirty-six ounces on the spot, two drops of croton oil were given, and later, a vapor-bath. The action of the bowels and skin were extremely free. That evening the patient woke up, spoke a few rational words, and recovered promptly in a week or ten days. It was found that three years before he had been in the Hospital with acute nephritis and dropsy: that his recovery from this attack had been apparently complete, certainly so far as symptoms were concerned; that he was a hard drinker of beer and a hard-working longshoreman; that for three days previously to the above-described attack he had been standing in water up to his arm-pits, transferring paving-stones from one boat to another, and freely imbibing beer. One reason for mentioning this case is that venesection was used, a remedy which has not yet been spoken of to-night, but one which is clearly indicated in some cases.

Dr. Osgood, in reply to Dr. Mimot, said he had purposely not used pilocarpine in this case, because the patient had shown a tendency to vomit, and knowing that pilocarpine frequently causes intense nausea, he did not think it advisable in a case of such gravity, to take the risk of irritating the stomach still more. The patient was naturally strong, and he therefore opened all the doors of escape for the uræmic poison, by following a course which in the result proved successful.

In reference to Dr. G. B. Shattuck's query concerning ether as preferred to chloroform, Dr. Osgood said he would not use the latter in any case, simply because through its use he had once nearly lost a valuable life, and had then and there determined never to use it again. In regard to the hot air-bath mentioned by various speakers, Dr. Osgood said he thought it must be extremely difficult to manage where a patient was seized by a violent convulsion every twenty minutes.

In reply to Dr. F. C. Shattuck's allusion to hypertrophy of the left ventricle as a means of diagnosis between an acute nephritis and an acute exacerbation of chronic nephritis, Dr. Osgood considers it a most excellent point.

Dr. E. G. CUTLER said that Dr. Osgood was remarkably fortunate in the excellence of the action of his drug, in that though he had given eight pills of one-eighth grain each of elaterium there had been no vomiting by his patient. His own experience had

been that such doses were very likely to produce severe and prolonged vomiting, though there was free catharsis at the same time.

In reference to the remark of Dr. F. C. Shattuck that hypertrophy of the left ventricle is diagnostic between acute and chronic nephritis, he would agree that in the main this was so, but cases have been observed and reported, where in acute diffuse nephritis following scarlet fever, both hypertrophy and greatly increased arterial tension had been observed. The latter being frequently an early and marked symptom. The hypertrophy has been observed to occur in four days or even less, and has been carefully noted in its progress.

Dr. C. F. FOLSON called attention to the fact that a considerable amount of albumen may be found in the urine of patients who have had repeated convulsions at short intervals of whatever origin; and these convulsions may precisely resemble those seen in Bright's disease, so that a positive differential diagnosis is not always possible from convulsions, coma and albuminuria only.

Dr. H. W. WILLIAMS said that his experience in the use of pilocarpine had been that the effect varies in different individuals. He uses it tentatively, at first in small doses. The action is usually rapid, and repeated small doses can be given until the desired effect is produced.

Dr. PRINCE stated that in his experience; cases of coma, the result of chronic Bright's disease, were always fatal, whatever the treatment.

Dr. F. B. HARRINGTON advocated venesection, especially in plethoric cases, stating that forty-eight ounces or more might be removed. The removal of that amount of blood, if followed by the introduction of an equal amount of inert salt solution, would greatly change the character of the blood. This method of treatment was followed by excellent results in cases of very profound poisoning by illuminating gas.

PERI-PANCREATIC HÆMORRHAGE.

Dr. J. J. PUTNAM showed a specimen of peri-pancreatic hæmorrhage which had proved fatal in four days. He said that the case would be reported at another time at greater length, and regretted the absence of Dr. Whitney and Dr. Fitz, who made the examination, and could demonstrate the preparation better than himself.

The patient was a middle-aged man who had suffered for five years from a severe form of hemiplegia. His final symptoms consisted in severe epigastric pain, varying in intensity, but not easily controlled by remedies, associated with epigastric tenderness, nausea and vomiting, excessive pallor with a bluish tinge, feebleness of the pulse, and eventually cardiac paralysis. For eight hours or more before his death the patient had been almost pulseless, breathing very rapidly and excessively cold, but consciousness had remained unimpaired up to a few minutes before the final termination.

— A stuttering son of Ham, whose wife was threatened with a miscarriage, rushed into a doctor's office, and in an excitable manner, demanded his immediate attention. "What is the matter, Pompey?" queried the doctor. "My-my-my wi-wi-wi-wife is-is-a-a-about to-to mis-mis-mis-misconstrue." — *Medical and Surgical Reporter*.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.¹

FIRST DAY.—EVENING SESSION.

THE HISTORY OF ABDOMINAL SECTION IN ALBANY. WITH A REPORT OF SEVENTY-FIVE CASES.

DR. ALBERT VANDERVEER prefaced his paper with remarks on the importance of physicians reporting every case of abdominal section which occurred in their neighborhood, together with the results, whether good or bad. The first case of the list of seventy-five in Albany was one of Dr. Marsh, and the patient recovered. Six other cases were also those of Dr. Marsh. It was a noteworthy fact that in his report of the case Dr. Marsh said sponges should not be used, and the peritoneum should be interfered with as little as possible. Dr. Vanderveer traced a relation between the greater success of later operations and improved methods of operating and cleanliness. He paid a warm tribute to Mr. Tate, whose qualities as a man, and labors as a surgeon had not, he thought, been fully appreciated in America.

DISCUSSION ON SALPINGITIS.

DR. WILLIAM GOODELL and DR. PAUL F. MUNDÉ, who were to discuss the subject of pathology and symptoms, sent letters expressing regrets at their inability to be present.

DR. CHARLES CARROLL LEE opened the discussion with remarks on

CAUSES OF SALPINGITIS.

He spoke of catarrhal salpingitis and true salpingitis, meaning by the former term inflammation of the mucous lining, and by the latter an inflammation involving all the tissues of the tube. Catarrhal salpingitis was the less serious, and occurred from any condition which would give rise to endometritis. It was rarely primary, but when it did occur as a primary affection it was due to cold, to repression of menstruation, and the usual causes of peri-uterine inflammation or congestion. True salpingitis was also due in its formative stage to extension of endometritis, and was more frequently due to septic influences than was the catarrhal form. The most severe form often occurred after abortion, when membranes remained to decompose and set up septic infection.

THE PROGNOSIS OF SALPINGITIS.

DR. GEORGE SEYMOUR, of Utica, in discussing this subject, said the simpler and more common forms of salpingitis, whether acute or chronic, might all be said to have a tendency, under favorable conditions, to recovery, to return to a normal state of physiological action. But that a very considerable percentage of cases of salpingitis had reached a stage at which the condition was very serious, must be admitted from the reports of many distinguished observers.

DR. FREDERIC A. CASTLE, of New York, discussed the

MEDICAL TREATMENT OF SALPINGITIS.

In most of his cases treated medically the patients had been seen by eminent specialists, who were unable to relieve them by drugs. Among measures which Dr. Castle had found beneficial, were to have the patient occupy a room separate from her husband, and relief of constipation by saline purgatives and

enemata. The tendency of enemata to lessen venous congestion would be enhanced by adding some saline substance to increase the specific gravity above that of the blood, so that osmosis would be into the cavity of the bowel. There should be absolute rest in bed, and restriction in the amount of food and drink. Among drugs which he had employed to meet different symptoms were veratrin, calomel, sulphuret of iron; instead of morphine for painful affections, a mixture of hyoscyamus and one of the bromides was safer. In massage, there was as much likelihood of forcing the fluid within the tube into the peritoneal cavity as into the uterine cavity. Besides, if the inflammation were severe, the patient would not submit to the massage treatment. It might be said that the medical treatment of salpingitis was not distinct from the treatment of inflammations of the pelvic tissues generally. To be of service, it should be employed early in the case. Owing to the difficulty of diagnosis, it was important that all pelvic inflammations should be treated judiciously from the first.

DR. WILLIAM M. POLK, of New York, discussed the

SURGICAL TREATMENT OF SALPINGITIS.

Dr. Polk said this part of the subject had often been gone over, and the most that he could do was to again review what he had said on former occasions. After some general remarks, he spoke of three forms of salpingitis which went on to collections in the tubes, pyo-, hamato-, and hydro-salpinx. Pus in the tubes should be treated as elsewhere in the body, cut down upon and removed. What had prevented surgeons doing so formerly was fear of the peritoneum; that is, fear that the operation would be exposing the patient to more danger than to allow the pus to remain. Improvements in the treatment of the peritoneum had rendered the operation almost as safe as when the pus collection was just beneath the skin. In pyo- and hamato-salpinx the opening should, in general, be made in the direction of pointing. Without such special indication, the central abdominal opening should be chosen. In parenchymatous salpingitis, that form in which there was great thickening of the walls of the tubes, the indications for treatment were less plain than in pyo- and hamato-salpingitis; yet, as we could not say that it would readily undergo resolution, and inasmuch as the patient's life was in danger, he thought we should operate. The next condition was that in which one tube contained pus, and the other, so far as the eye could detect, was sound. Many surgeons had been disposed to extirpate the former and leave the latter. Dr. Polk thought it might be shown that both tubes should be removed. At any rate, they should both be removed unless the surgeon wished to run the risk of having to open the abdomen twice, for the apparently well tube was very apt, after removal of the diseased one, to become filled with pus within a period varying from six months to a year. If there were present active endometritis, it certainly would be unsafe to leave the other tube. If the endometrium were sound, we might leave the second tube, especially if we were anxious not to unsex the patient.

Regarding removal of the tubes for catarrhal inflammation, he was of the opinion at present that it should not be done, for doubtless every man present had seen such cases go on to absolute recovery.

¹ Continued from page 181.

There was a class of cases in which the tubes, while not closed, were bound down by adhesions, could not expand properly at the menstrual period, when they naturally became engorged, and they then caused much pain. In this condition, Dr. Polk thought we were justified in opening the abdomen and breaking up the adhesions, freeing the uterus and tubes, so that they could undergo their monthly physiological change without causing the patient so much suffering. He thought this might be done, and the risk of re-formation of adhesions be avoided by measures which he could not then discuss.

Dr. Castle had very properly pointed out the dangers attending Schurz's method of massage in collections of fluid in the tubes.

Dr. W. GILL WYLIE discussed

THE RESULTS OF OPERATIVE TREATMENT.

He first made some remarks on papers previously read, and said that in his experience the great majority of cases of salpingitis demanding operative interference were caused by sepsis following abortions and labors, and that it was a mistake to say the majority, at least, of those demanding operations, were due to gonorrhoea and catarrhal inflammations.

In his paper, Dr. Wylie showed that since strict cleanliness had come to be observed, the results of operations for salpingitis had been much more favorable. In his paper he gave the results of seventy-eight laparotomies, all told, which he had performed during the year: eight hysterectomies for uterine fibroids, one death; fifteen laparotomies for large ovarian tumors, one death from nephritis; forty-one for disease of the tubes or fibroma, one death from nephritis. Altogether, he had operated for removal of the uterine appendages in one hundred and fifteen cases, six deaths. In pyo-salpinx it was the only treatment. In hydro-salpinx, it alone would often relieve pain. About three per cent. of all cases menstruated after removal of both tubes, but in general these were the cases in which there were the greatest adhesions, and it was doubtful whether all of the tube had been removed.

Dr. ALBERT VANDERVEER also discussed briefly the results of operative treatment, and said we should not lead our patients to expect too much in the way of immediate results after removal of the uterine appendages for pyo-salpinx. His own experience regarding hystero-epilepsy was that this symptom had not been cured by removal of the uterine appendages. When the operation was done the appendages should be removed thoroughly.

TREATMENT OF COMPLETE PRICIDENTIA OF THE WOMB BY ALEXANDER'S OPERATION.

Dr. CHARLES CARROLL LEE read the paper, and expressed the hope that by the aid of Alexander's operation we might cure the most extreme conditions of pricidentia.

Dr. W. POTTER, of Buffalo, read a paper on

THE MANAGEMENT OF PELVIC INFLAMMATIONS IN WOMEN,

in which he made general remarks on pelvic inflammations, and then considered the management of their residue. In the paper he underscored the following points:

(1) The importance of early attention to even minor pelvic inflammations.

(2) Suggested a simpler classification; namely, into simple pelvic inflammation, or pelvic cellulitis; second, compound pelvic inflammation, or cellulitis-peritonitis; and third, complicated pelvic inflammation, in which the appendages were involved.

(3) The influence which the inflammatory remains exerted on the health of the woman.

(4) The great value of support and pressure in their treatment.

(5) A thorough trial of all other measures before resorting to surgery.

Dr. W. M. POLK then read a paper on

VAGINAL HYSTERECTOMY, WITH A REPORT OF EIGHT CASES.

He had performed the operation in the eight cases for cancer of the uterus, and it was only for this disease that he discussed the operation. Statistical arguments were based on the seven hundred and thirty-two cases collected in a Philadelphia journal. We had reason to believe that the next like series of cases would show a much smaller death-rate. The results were best shown by the statistics of Martin and Fritz. Dr. Polk then described in detail his method of operating. The great danger was from shock caused by a prolonged operation.

SECOND DAY.—MORNING SESSION.

Dr. WILLIAM H. THOMPSON, of New York, read a paper entitled

DISTINCTION BETWEEN FUNCTIONAL AND ORGANIC DISEASE OF THE NERVOUS SYSTEM,

in which he drew the following distinction between an organic and a functional nervous disease: the former is accompanied by characteristic, invariably present, and recognizable organic change or changes in nerve-texture; the latter is a disease in which there is no such invariable organic change which has yet been made out.

Examples of the former were myelitis, meningitis and peripheral neuritis. Of the latter were chorea and epilepsy. True functional diseases presented the grand distinctive feature of intermittency. For brevity, and to make his views understood, he confined his remarks to the causation of an epileptic fit. A peripheral irritation excited central structures and caused a fit. The irritation again arising, a second fit occurred. In the intervals between the fits there was no change in the central nerve structure, and the fit arose from temporary disordered function. The habit might become more or less fixed, just as one could contract a mechanical habit, which was easy of repetition when the peripheral or external stimulus was presented, yet there was no structural lesion. This was true even of those cases of epilepsy in which the afferent impulse proceeded from a tumor within the cranial cavity. True functional nervous disorders were invariably peripheral in their origin, never central.

For treatment of functional nervous disorders, search for the point of afferent irritation.

THE DIETETIC TREATMENT OF GOUTY DIATHESIS.

Dr. WILLIAM H. DRAVER, of New York, read the paper. After defining the terms diathesis, gout and gouty diathesis, he briefly referred to the lesions and then took up the subject of dietetic treatment. Often a distinction could not be made clinically between the rheumatic and the gouty diathesis, while the so-called

lesions of the two diseases might justify such a distinction. It had come to be a common impression that nitrogenous foods were inappropriate for the gouty, while hydro-carbons should be used. Dr. Draper's experience went to prove the contrary, and he forbade the use of fats, sugars and starches, while he recommended nitrogenous articles. It was also the common belief that fruits were good for these patients, but he had found them unable well to digest them. The theory of uric acid being the essential cause of the disease, had led to the false treatment by exclusion of nitrogenous foods. Beer and wine should be avoided. If spirits were used, dry champagne would be found among the least harmful for these patients.

REPORT OF THE COMMITTEE ON HYGIENE.

DR. E. V. STODDARD read the report. The Committee had, during the year, given its principal attention to organizing local committees, consisting of from three to five, in the several counties, which should act in concert with the State Committee. They did not favor the view that local Boards of Health should be composed entirely of physicians; two or three physicians were sufficient, while the remaining members of the Board should be composed of energetic, intelligent business men. Boards of Health and Health Officers should not be under political influence. A communication from the Medical Society of the County of New York treated of the evil of long tubes in nursing bottles, and of measures to prevent the sale of adulterated milk.

TREATMENT OF PENETRATING GUNSHOT WOUNDS OF THE CRANIUM.

DR. JOSEPH D. BRYANT, of New York, in this paper considered only local treatment. The commonly accepted indications for local treatment were: arrest of hemorrhage, elevation of depressed bone, removal of foreign bodies, establishment of good drainage, combatting inflammation.

Should the ball be removed from the brain? In statistics of 236 cases, it was not removed in 170, and was removed in 66. Of the former 54 per cent. died; of the latter 43 per cent. died. Of the former, again, only 20 per cent. recovered without sequelæ; of the latter 41 per cent. made a complete recovery.

Force should never be used in probing. The induction balance and telephonic probe were instruments which best enabled us to definitely locate the ball. If the ball could not be located it should be permitted to remain unsought for. Fragments of bone in the course of the wound should be removed. The bullet should be removed as soon after the wound as the patient's condition would permit. If symptoms developed in an old case one should seek to remove the ball.

The wound should be so placed as to facilitate drainage. Drainage could be best secured by making a counter opening, and by enlarging somewhat the bony rim at the point of entrance. In one case Dr. Bryant used numerous horse-hairs as a drain.

DR. JOHN H. GIRDNER, of New York, made a

DEMONSTRATION WITH THE INDUCTION BALANCE AND TELEPHONIC PROBE.

He had so far perfected the induction balance as to be able to detect a metallic substance in the brain an inch and a half distant from the scalp, and he hoped to be able to make the instrument still more perfect

in the future. The telephonic probe was already a perfect instrument; when it came in contact with the piece of metal in the body it invariably gave a signal. It was a curious fact that the sound given forth by the probe when it came in contact with metal in the human body differed in intensity in different persons, and in the same persons in different states of health, but it was in all sufficiently intense to be plainly noticeable.

EXTENSIVE CRANIAL FRACTURE; CONSIDERABLE LOSS OF BRAIN SUBSTANCE COMPLICATED WITH FUNGUS CEREBRI.

DR. A. ROSS MATHESON presented a young man who, when a boy, was tramped upon by a horse, causing the injury indicated in the title of the paper. He was now engaged as a compositor in financial statistics, which required a good deal of mental work. He showed no effects from the injury.

FRACTURE OF THE SKULL WITH DEPRESSION.

DR. HENRY FLOOD, of Elmira, read the paper, in which he gave, among other observations, the results of experiments going to prove that fracture of the outer plate of the skull without injury to the inner table was of so rare occurrence that it was hardly worth considering in practice. The frontal sinus occupied a smaller space than was generally supposed.

DR. GLASS related the case of a street car driver who shot himself in an attempt at suicide, the ball passing to the opposite side of the head. Within two months he resumed his ordinary occupation. The ball could still be located by the induction balance about an inch from the skull. He asked Dr. Bryant whether he would, under the circumstances, the man being well, cut down and remove it.

DR. BRYANT said that if the induction balance should show that the ball was changing its position, he would, through fear of its interference with important nervous centres, remove it, but if it was shown to remain stationary he would leave it.

DR. CHARLES STOVER, of Amsterdam, then read a paper entitled,

THE INTERDEPENDENCE OF LOCAL, STATE, AND NATIONAL HEALTH BOARDS; A PLEA FOR THEIR UNIFICATION.

(To be continued.)

THE NEW YORK ACADEMY OF MEDICINE. SECTION ON PEDIATRICS.

STATED MEETING, January 25, 1888.

DR. A. CAILLE presented a

CASE OF GENERAL MUSCULAR CONTRACTURE

in an infant of six weeks, which had been seen by him for the first time that afternoon, and said that it seemed to him that the condition present was probably due to an arrest of development *in utero*. The parents were both healthy, and this was the third child of the mother. The other two children were strong and well-developed in every way. This infant was born at full term, and the head was comparatively large, with a decided flattening on one side of the cranium; but the rest of the body was small and shrunken in appearance. The jaw, which was turned somewhat to one side, could be opened to only a very limited ex-

tent, so that the child was not able to suckle, and there was general contracture of the muscles of both the upper and lower extremities.

Dr. A. JACOB, after an examination of the child, (which was exhibited to the section), said that he could not see any evidence of arrest of development, and that the condition present appeared to him to be the result of a meningo-encephalitis occurring during fetal life. The contracture of the jaw somewhat resembled that seen in incipient trismus, although the spasm was not so marked as in that affection. The appearance of the cranium was very much like that met with in cranio-tabes, in children a year or more old. He thought it was doubtful whether galvanoelectric treatment would be of much service in such a case, and that an unfavorable prognosis must be pronounced; although a certain proportion of children presenting the condition noted in this infant, which was undoubtedly very rare, recovered.

The chairman, Dr. J. LEWIS SMITH, exhibited a

CASE OF INFANTILE PARALYSIS.

which, in his opinion, was the result of polio-encephalitis. The child was two years old, and had always been perfectly healthy, with the exception of an attack of diarrhoea, up to May last, when, at the age of sixteen months, while apparently quite well, it was seized with violent convulsions, which lasted from 6 p. m. to 3 a. m., and were accompanied with considerable *ir-regular* movement. After the stupor commonly following severe eclampsia had passed off, it was found that the child had complete paralysis of the muscles on the left side of the body, including the facial muscles on that side. The recovery from the facial paralysis was complete, and took place rapidly, while there had been a gradual improvement as regards the muscles of the upper and lower extremities. At the present time the child was able to walk, though partly dragging the left leg, and there was still a spastic condition of the toes on the affected side.

Dr. Smith said that it seemed to him that some of the cases resembling this which had been reported as due to cerebral inflammation were in reality instances of cerebro-spinal meningitis. Since 1871 epidemic cerebro-spinal meningitis had obtained a permanent foothold in this city, and New York children are, therefore, constantly liable to be attacked with it. In the present case, however, the patient resided on Long Island, and, consequently, not being subject to influences giving rise to cerebro-spinal meningitis, he thought the latter might be excluded here. It was thus evident that the condition noted must have had a local cause, and, judging from the history of the case and the symptoms described, particularly the fever accompanying the sudden attack of eclampsia, he was inclined to the opinion that it was one of infantile cerebral paralysis or polio-encephalitis, described by Strumpell. One of the characteristics of this affection, according to the author named, was that tendon reflex was not only not impaired, but became exaggerated, and this was found to be the case in the present instance.

Dr. B. SEYMOUR said that it appeared to him that simple meningeal hemorrhage would offer a more satisfactory explanation of the phenomena noted in this case than polio-encephalitis. As a result of the latter condition there almost always followed more or less mental impairment, while after meningeal hemorrhage

the condition of the intellectual faculties, as a rule, remained unaffected. Still, it was by no means certain what the exact diagnosis was here, and he thought it would be impossible to arrive at any definite conclusion until an investigation of the electrical relations of the case had been made.

Dr. A. JACOB said that after hemorrhage the presence or absence of mental impairment would depend, first, on the size of the clot, and, second, upon the amount of consecutive inflammation. When there was mental impairment it was to be inferred that there had been considerable encephalitis following the hemorrhage. In this case he said he was very much inclined to think that the severe convulsions gave rise to the hemorrhage, which caused the paralysis. As to the advantage of studying the electrical relations here, he did not believe it could throw much light upon the diagnosis.

Dr. SMITH stated that it was the marked febrile movement described as accompanying the eclampsia which had principally led him to decide in favor of polio-encephalitis.

Dr. FRANCIS P. KINNICUTT said that he believed that many cases like this were due to embolism. Abercrombie, in reporting a number of cases of infantile paralysis recently in one of the English medical journals, had expressed the opinion that a certain proportion of them depended on embolism, and Goodhart, while acknowledging other sources of origin in many instances, also ascribed some of the cases to this cause. It seemed to him, therefore, that the possibility of embolism should always be taken into consideration, and particularly where the children were in an asthenic condition, as after attacks of the exanthemata.

Dr. JACOB said that in debilitated states resulting from the eruptive fevers we should expect thrombosis, rather than embolism. If there were heart-disease, or even a broncho-pneumonia, we might believe that an embolus was the cause of the paralysis, but otherwise he thought this was to be excluded. Thrombosis, however, was a very common result after exhaustive diseases.

Dr. KINNICUTT said that he should have explained that in embolism occurring in the asthenic conditions referred to, he should attribute the embolism to thrombosis located in some distant part.

Dr. SMITH said that in this case thrombosis and embolism could be excluded on account of the previous good health of the child.

Dr. LANDON CARTER GRAY, of Brooklyn, said that the exact diagnosis of hemiplegia in children was attended with much obscurity. Personally, he was very doubtful whether the condition described by Strumpell occurred very often, and he believed that the statements which this authority made, were founded to a large extent on mere speculation. The most that we could say was that in children the site of the trouble was apt to be in the cortex of the brain, and usually in the motor region. It was generally impossible to make a differential diagnosis, and at autopsies he had more than once had occasion to congratulate himself that he had not attempted to decide between encephalitis and meningitis during life. The whole matter was entirely uncertain, and in the present state of our knowledge, on account of the great liability to make mistakes, he thought it was more scientific not to venture upon a precise diagnosis in such cases.

DR. A. JACOBI was to have read a paper on

SEPSIS IN THE NEWLY BORN,

at this meeting, but in consequence of the nature of the cases just presented and discussed, and their intimate connection with the subject of the paper of Dr. Seibert, also announced for the same evening, he asked to be excused, and expressed the opinion that it would be more advantageous to devote the whole session to the subject of infantile paralysis.

DR. A. SEIBERT then read a paper entitled

A CONTRIBUTION TO THE STUDY OF CEREBRAL PARALYSIS IN INFANCY.

After a few introductory remarks he said that in 1885 he was called upon to examine an infant two-and-one-half months old. It was the seventh child of its mother, all the others having been healthy children, and there was no evidence of syphilitic or tubercular trouble. The mother stated that during the pregnancy when she was carrying this child, she scarcely ever felt life, and that when the infant was born it was asphyxious and had the cord tightly wrapped twice around its neck. It was very different from her other children, being small and flabby, and for two months it never stirred or cried. When two-and-one-half months old it had an attack of capillary bronchitis, and it was at this time that it first came under Dr. Seibert's notice. At the end of ten months it is still practically in the same feeble condition. It lay quietly on its back, the skin was wrinkled, and the respiration was noted to be very largely diaphragmatic in character. There was no evidence of craniotabes. The pupils were narrow and equally dilated, and the constant expression on the child's face was that of a dreamy, vacant stare. When the body was raised to an upright position, the head would fall to which ever side on which there was the greatest incline. The intercostal spaces were very narrow, the intercostal muscles evidently took but little part in the act of breathing, and there was a deep furrow in the diaphragm. The muscles of the neck were but mere strings, and there was in general an almost complete absence of muscular power. The infant never had any convulsions.

From the phenomena thus presented, there could be little doubt that there was an atrophied condition of the brain, and Dr. Seibert endeavored to find out the cause of this. As the condition noted had existed from birth, meningitis was at once dismissed; for if it had been due to meningitis, the latter must have occurred during fetal life, and so far as he was aware, this was something which had never been met with. Neither did he believe that the trouble was due to hæmorrhage. The child was small, flabby and atrophic when born. All the symptoms denoted an atrophic condition of the whole body, including the brain, at the time of birth and after birth. The muscles of the neck were more completely atrophied than any others, and in this connection it was significant that the infant had been born with the cord wound twice about the neck.

In this constriction of the neck by the cord, it seemed to him, was to be found the solution of the problem presented. By means of this constriction the blood-supply of the head and brain had been to a great extent cut off, and this would fully account for the cerebral atrophy and the general lack of nutrition in the child's body. At the time of birth the blood-

vessels of the head, which had long been comparatively empty from the pressure of the cord around the neck, suddenly became filled when this was removed, and hence the asphyxia noted.

At fourteen months of age the child died from another attack of capillary bronchitis, and when the brain was examined after death it was found that the layer of white matter was very thin, and the diagnosis of cerebral atrophy was abundantly confirmed. In the course of his experience, he said that he had met with four cases altogether in which there was congenital atrophy of the brain, but this was the only one in which he had been able to secure a full clinical history, and verify the diagnosis by autopsy.

The second variety, he went on to say, was more common than the first, just treated of, and of this he gave a detailed description of two cases. In one of these a post-mortem examination was made, but not in the other. In this second class of cases the symptoms were similar in character to those met with in the first; but here they were brought about by pathological changes; namely, meningitis with exudation, arachnoid thickening, and sometimes moderate hydrocephalus. The results of the meningitis caused atrophy of the brain. The symptoms of defective innervation always remained the same whether the cerebral atrophy were congenital, or was the result of subsequent meningitis.

The third class of cases mentioned was characterized by incessant crying and moaning, with muscular contractures and sometimes permanent opisthotonos, though there were no general convulsions. The condition was due to chronic meningitis, steadily increasing, and causing abundant exudation over the cortex, but running its course without febrile movement. He related two cases of this kind, occurring in a brother and sister, and in one of them the diagnosis was confirmed by autopsy. After lasting for several months, the affection terminated in heart-failure; the temperature in one case falling to 96° F., and in the other to 94°. In the case in which the post-mortem was made there were no tubercles nor tubercle-bacilli found.

In conclusion, Dr. Seibert said that in these three classes of cerebral paralysis of infancy the clinical manifestations are all due to atrophy of the brain, although, in the first, the original cause of trouble was insufficient blood-supply; in the second, acute meningitis; and in the third, chronic meningitis.

—The total amount of life insurance in force in the world at the end of 1886 is reported by an expert to have been seven and a quarter billion dollars. Of this the United States had over one-third, more than either Great Britain and Ireland, or the whole continent of Europe. Up to 1883, Great Britain and Ireland headed the list.

—The *Pacific Record* figures it out that of one thousand graduates from collegiate institutions, seventy-five only make for themselves a name and prominence in their calling. About two hundred, having business qualifications, become rich by their practice, and by judicious investments. Four hundred abandon, in whole or part, their profession, for some more lucrative business, and the balance struggle with mediocre ability for a bare subsistence, and a wearying effort to keep up an appearance before the people.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, FEBRUARY 23, 1888.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, week ly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States and Canada; \$6.00 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 94 Boylston Street.

All letters containing business communications, or referring to the publication, subscription or advertising department of this journal, should be addressed to the "Manager of the Business Department," Medical and Surgical Journal, 94 Boylston Street.

Remittances should be made by money-order, draft, or registered letter, payable to

CUPPLES AND HURD,
94 BOYLSTON STREET, BOSTON, MASS.

A NEW TEST FOR THE PRESENCE OF HYDROCHLORIC ACID IN THE GASTRIC JUICE. THE RECENT DISCUSSION BEFORE THE ACADEMY OF MEDICINE.

PROFESSOR GERMAIN SÉE, who considers all true dyspepsias as functional disturbances due to a perturbation in the chemical processes of stomachal digestion, has lately read a long communication before the Academy of Medicine, Paris, in which he reiterates the views expressed in his work on "The Dyspepsias," published in 1881. A large part of the indigestions being due to lack of the natural acid of the gastric juice, he would designate this kind of dyspepsia by the name *anachlorhydria*. This deficiency in hydrochloric acid is especially noticed in carcinoma of the stomach with or without dilatation, and in certain dyspepsias called *mucous*, and especially in those which result from inanition or marasmus. Where it has been clearly determined by repeated examinations of the contents of the stomach removed by the siphon that hydrochloric acid is lacking, (and such examinations Professor Sée always makes, before he undertakes the treatment of a difficult case of gastric disease), there is a clear indication for the medicinal administration of this acid, with or without pepsin. The best test for the presence, in however feeble quantities, of hydrochloric acid in the contents of the stomach is that recently proposed by Günzburg, and which, Professor Sée thinks, ought henceforth to settle the long dispute as to whether in normal stomachs the free acid of the gastric juice is hydrochloric or lactic.

Günzburg's phloro-glucine-vanillin test is as follows: A strong alcoholic solution of phloro-glucine and of vanillin is prepared in the proportion of two parts of the first to one of the second. In adding hydrochloric acid to this solution, there is a precipitate of scarlet red crystals. If the hydrochloric acid is very dilute it is well to employ only a few drops of the test liquid and the fluid under examination. This is evaporated in a watch-glass or porcelain crucible, by means of a gentle heat. At the sides of the liquid undergoing evaporation, there is observed a slight

rosy tint, which is also quite perceptible by lamp-light. This is a very delicate test, for while litmus requires the presence of at least one per cent. of the acid in the liquid under examination in order well to respond, Günzburg's test reveals the presence of hydrochloric acid if the solution is not stronger than 1-5000, and is not at all influenced by the presence of organic acids, such as lactic and acetic acids.

In the acid dyspepsias, characterized by heat in the stomach, pyrosis and cardialgia, hydrochloric acid can only aggravate the symptoms; here an azotized diet, inert powders and alkalies are indicated. Professor Sée does not recognize any other form of dyspepsia but those of a chemical nature; the other kinds are "pseudo-dyspepsias," and comprise what he treats of in his works under the head of "nervous and motor dyspepsias," "constitutional and toxic dyspepsias," and "gastro-intestinal atony."

At the second meeting of the Academy, held January 24th, the paper of Germain Sée was discussed by Dujardin-Beaumetz, Constantin Paul, Laborde and others.

Dujardin-Beaumetz was not disposed to place much stress on the chemical examination of the contents of the stomach in dyspeptics, with reference to determining the minimum or maximum amount of hydrochloric acid secretion. Many causes, apart from digestion, modify the production of this acid. Thus the acidity of the gastric juice is diminished by abundant perspirations, and in females by menstruation; renal and nervous perturbation also markedly modify the gastric juice. He believed, moreover, that the word dyspepsia had no more right to be retained in treatises on Practice of Medicine, as a nosological entity, than the word vomiting, both being only symptoms of a variety of morbid states.

Constantin Paul alluded to the valuable discoveries of Debove and Bouchard, on dilatation of the stomach and its consequences, as throwing light on the pathogeny of many forms of dyspepsia, and referred to the value of Rommelere's urea test in diagnosing simple from malignant forms of gastric disease.

Laborde maintained that the view which he had entertained from the commencement of his physiological studies, and which had been confirmed by experiments of his own, namely, that the stomach in the normal state contains lactic and not hydrochloric acid, had not been overturned. The phloro-glucine-vanillin test, which he was disposed to make little account of, in no way invalidates this conclusion.

Professor Sée, in closing the debate, admitted the presence of free lactic acid in the gastric juice, but affirmed that hydrochloric acid predominates in the stomach during digestion, as can easily be determined by analyzing the contents of the stomach removed half-an-hour or so after a meal of azotized substances.

—A relatively large number of cases of typhoid fever has occurred recently in the Royal Barracks, Dublin.

REPORT OF NEW YORK STATE BOARD OF HEALTH.

THE annual Report of this State Board of Health is now ready for transmission to the Governor. It gives the total number of deaths in the State during 1887, as 96,453. Of this number 35,114 were of persons under five years of age. Phthisis caused 11,609 deaths; diseases of the nervous system, 9,957; typhoid fever, 1,327; and small-pox, 175. The aggregate population upon which the figures given are based is 3,500,000, the death-rate being 23 per 1,000 inhabitants; indicating, it is said, an average longevity of 43.74 years. The other vital statistics for 1887, excluding New York, Brooklyn, Yonkers, Albany and Buffalo, are given as 46,857 births and 22,966 marriages.

The report embodies the recent report of the Board to the Governor, in regard to the condition of the Quarantine Station of the port of New York, and recommends that the Health Officer, in conjunction with the State Engineer, be directed to prepare plans for such remodelling of the station as is required for its more thorough efficiency, and that these plans be submitted to the Board for approval. Also, that in case a bill is passed by the Legislature appropriating moneys for repairing the Quarantine Station, it so read that such repairs are to be made on plans and estimates prepared and approved as above.

Among the other recommendations made in the report are the following: That power be given to the Superintendent of Public Instruction to enforce through trustees the sanitary improvement of schools; that the Supreme Court, as well as County Judges, be empowered to approve regulations of the Board as to the water-supply for cities; and that a more thorough organization of local health boards be provided for.

PLEURO-PNEUMONIA IN CATTLE IN NEW YORK.

Professor Law, chief inspector of the Bureau of Animal Industry in the State of New York, states that there is no unusual ground for the alarm which is said at present to prevail among dairymen and other owners of cattle in regard to pleuro-pneumonia. Owing to the active exertions of the deputies and inspectors in endeavoring to stamp out the disease, however, more than the usual number of cases are being reported; and this has created the impression that it was rapidly spreading. As a matter of fact, there has been an actual decrease in the number of affected animals, owing to the work of the Bureau in purchasing and causing to be slaughtered all cattle that have been exposed to the contagion. The quarantine system now established in the counties of New York, Westchester, Kings, Queens and Richmond, is absolute. Not an animal can be moved from one stable to another without a permit from the Bureau, nor can an animal be sent to an abattoir for slaughter, until such a permit has been obtained. Even then the butcher is

not allowed to kill the cattle except in the presence of an inspector, who takes possession of the lungs for purpose of determining whether the animal had been diseased. Almost every head of cattle in the five quarantined counties has been registered upon the books of the Bureau, and within a few days the registry of the stock will be complete; each animal having attached to its ear a tag bearing a number which corresponds with a number on the books. As a rule, owners are said to be satisfied with the terms made by the Bureau's agents; but on Long Island there is some dissatisfaction among certain advocates of inoculation. Professor Law is opposed to this system, believing that it would never eradicate the disease, and since the Government is willing to pay for the slaughtered animals, he thinks the owners should be glad to assist in stamping out the disease, rather than wish to perpetuate it by means of inoculation. He is confident that under the system now in operation, the disease will disappear within a few months.

TREATMENT OF TYPHOID FEVER BY SMALL DOSES OF CORROSIVE SUBLIMATE.

CORROSIVE sublimate has the reputation of being the best germicide yet known, and typhoid fever is now generally regarded as a germ disease. Therefore, it is natural that clinical experimenters should have endeavored to avail themselves of the parasiticide properties of this mercurial salt in typhoid fever. Unfortunately, however, the doses in which the mercuric chloride is fatal to bacteria are rather hazardous for internal administration, by reason of the irritation which they occasion in the alimentary canal, as well as by reason of the depression of the vital forces sometimes consecutive to therapeutic mercurialization.

In a communication to the Paris Society of Biology, October 29th, Roger and Charrin offer reasons for believing that the bichloride retards the growth and development of the typhoid bacillus (Eberth's bacillus) in much smaller doses than has been supposed; one part to twenty thousand markedly hindering the multiplication in nutrient media of these microbes. "Moreover," says M. Charrin, "in starting with a minimum dose of an antiseptic capable of arresting life in a micro organism, one may diminish this quantity by a third, even by one-half, and consequently, diminish in this proportion the noxious action which might be exercised on the patient by the antiseptic employed, while, at the same time, a considerable influence is retained on the infectious agent which it is desired to combat, for its life, development, and function are to some degree impeded thereby." The same writer argues further, that if the vitality of these microbes is not compromised by the solutions of 1-30,000 to 1-60,000 of the corrosive chloride, which he recommends for internal administration, their functions will, nevertheless, be in a measure annihilated by subjecting the bacilli to the presence of the toxic agent; and among these functions, it is now held,

since the researches of Gautier, Bouchard, and others, that the secretion of poisonous ptomaines has an important place.

Dr. Edouard Rondot has published in the *Gazette Hebdomadaire des Sciences Médicales* the results of his hospital experience with typhoid fever, as treated the past year by small doses of corrosive sublimate often repeated; the daily quantity of this salt prescribed for an adult patient not exceeding five milligrammes, or about one-twelfth of a grain. He reports twenty-three cases thus treated, all of which were characterized by their gravity, and all of which, except two, recovered, these two having been brought to the hospital in an advanced stage of the malady. In the twenty-one cases that got well, there was, he affirms, a shortening of the term of the disease, and a marked attenuation in the intensity of the principal symptoms under the sublimate treatment. There was no unfavorable complication, such as diarrhoea, salivation, or debility — complications which have often been imputed to mercurial treatment. Rondot prescribes the bichloride in an alcoholic potion, with balm water, syrup of punch, and extract of cinchona. This formula, which, as it stands, would be impossible of execution in this country, may be thus rendered :

Anise cordial	90 grammes.
Simple elixir	30 grammes.
Extract of cinchona	2 grammes.
Bichloride of mercury	2 to 5 milligrammes.

Dose, a tablespoonful every two hours.

Concurrently with this medicinal treatment, he gives plenty of nourishment in the form of milk and broths, and vinous lemonade. He also gives quinine in fractional doses "to slow the movement of disintegration, without diminishing the oxidations." The average duration of the disease under this treatment has been fifteen days."

Rondot believes that his sublimate potions do good principally by attacking the microbes in the blood, where, however, they are relatively few in number. For a local effect on the alimentary canal, it would be well, he thinks, to employ, besides, a microbicide which is almost completely insoluble, like naphthol.

We are not disposed to expose ourselves to disappointment by expecting precise specific results from this bichloride treatment of typhoid fever, not having yet realized our very moderate expectations from the treatment by naphtholine. Are we to arm ourselves with a different weapon for the pursuit of this microbe according to the nature of his lair, whether in the blood, in the alimentary canal, or in the tissues themselves, as the spleen, mesenteric glands, etc.? Under such circumstances, the last state of the patient, we cannot but fear, runs a chance of being worse than the first.

MEDICAL NOTES.

—The accounts in regard to the condition of the German Crown Prince are far from reassuring and

lead us to expect a not very distant confirmation of the unfavorable prognosis already plainly expressed in our editorial of November 17, 1887.

BOSTON AND NEW ENGLAND.

—Both branches of the city government have passed without a dissenting vote an order requesting the Trustees of the City Hospital to present estimates for an Out-patient Building.

—On the night of the 15th inst., a gentleman, aged sixty-eight years, residing at Oak Knoll, Danvers, Mass., left his bed while asleep, and walked forth from his house clad only in his night-shirt. He was found the next morning frozen to death, about a quarter of a mile from his house. The thermometer marked from eight to ten degrees below zero that night. The same man, who had been afflicted with somnambulism for some years, is said to have nearly perished in a similar way once before. He went from his house one cold night, but was observed and brought back, having, however, to suffer the amputation of a finger that was frozen.

—The late Gardner S. Burbank, in his will, made generous provision for the establishment of a hospital in Fitchburg, Mass. After providing for certain bequests, he leaves the income of the residue of his estate to Mrs. Burbank during her life. After her decease, the property goes to found and maintain a hospital for care of the sick. The money is left without restriction, but with two suggestions only. First, that at least \$100,000 be devoted to the purchase of necessary land, and the erection of a substantial and commodious hospital building. He also requests that those who are able to pay for services rendered in the hospital be subjected to such reasonable charges as are usual in similar charitable institutions, but those who are in poverty and sickness shall ever be received and cared for kindly and tenderly, "without money and without price," and without regard to color or nationality. In closing, he states that provision for the foundation of the hospital is made "by request of my wife, whose good judgment has so greatly aided me in all my affairs and purposes of my life." The estate is mostly personal property, and the amount is not yet known.

NEW YORK.

—A letter of Dr. A. E. MacDonald, superintendent of the city insane asylums, written in response to a request from the Mayor for information upon the subject of the causes of insanity among certain artisans, having been referred to the president of the Board of Health, the latter has prepared a statement, in the course of which he says: "The question of cigar-making in tenements is so intimately connected with certain commercial and social problems that the statement is hardly credited as an honest one that there are absolutely no trustworthy facts of any kind, other than assertions, to show whether cigar-making in tenements is more injurious to the health of the

workman than cigar-making in large shops, or the contrary; and yet this is the truth. . . . As regards the statistics of insanity furnished by Dr. MacDonald, it is to be noted that the so-called 'contemplative trades,' in which the workmen lead a sedentary life, and are engaged in some mechanical operation which leave their minds free to muse on other subjects while they are at work have always furnished a large proportion of cases of insanity. This was noticed among shoemakers and tailors a hundred years ago, and with the immense recent growth of cigar manufacture the cigar-makers may fairly be classed with those trades, it being far more probable that the monotony of these occupations brings about insanity than the sleeping, cooking, and working in the same room, which many an artist or literary worker also does. . . . I feel justified in saying that all the information now before the Board leads us to believe that there is nothing in the business of cigar-making which renders it especially objectionable in tenement houses. Personally, I am inclined to the opinion that if any trade should be excluded from the tenement houses it is that of tailoring, owing to the greater liability of textile fabrics to carry contagion than exists in the case of any other articles of manufacture."

— On a single day, February 13, ten cases of small-pox in cheap lodging-houses were reported in Brooklyn, and of these nine from one house. The building was thoroughly fumigated by the sanitary authorities, and thirty of the other inmates were vaccinated and locked up until it could be seen whether any further cases would be developed. On the 15th of the month there were eighty cases of small pox in the county hospital at Flatbush, and it is said that when full it is capable of accommodating only one hundred patients. In the future all the cheap lodging-houses in Brooklyn will be inspected daily by officers of the Health Department. They have been found, as a rule, to be dirty and over-crowded, and this step is a wise precaution.

Miscellany.

THE HUMAN BREATH A POISON.

THE Paris correspondent of the *Medical Press and Circular* reports that at the last meeting of the Académie des Sciences, Professor Brown-Séquard referred to some experiments he had conducted with a view to determine what, if any, were the toxic effects of the human breath. In condensing the watery vapor coming from the human lungs, he obtained a poisonous liquid capable of producing almost immediate death. This poison is an *alkaloid* (organic), and not a *microbe* or series of microbes, as might have been imagined. He injected this liquid under the skin of a rabbit, and the effect was speedily mortal. The animal died without convulsions; the heart and large vessels were engorged with reddish blood, contrary to what is observed after ordinary death, when the quantity of blood is moderate and of a dark color.

In conclusion, this eminent physiologist said that it was fully proved that expired air contained a volatile toxic principle far more dangerous than the carbonic acid, which was also one of its constituents, and that the human breath, as well as that of animals, contained a highly poisonous agent.

MASSACHUSETTS MEDICAL SOCIETY.

COUNCILLORS' MEETING, FEBRUARY 1, 1888.
REPORT OF COMMITTEE ON MEDICAL DIPLOMAS.

At the meeting of the Councillors in October last, Dr. Bowditch stated that a physician who had received his diploma from a Homeopathic Medical School, had renounced homeopathy, and was desirous to become a Fellow of the Massachusetts Medical Society. He was willing to submit to the examination for membership, but was informed by the Censors that he was ineligible thereto in not having a diploma from a "recognized" school. He could only obtain this diploma by a prolonged and expensive attendance at such a school.

The following questions proposed by Dr. Bowditch, were referred to the Committee on Medical Diplomas:

First, The papers relative to Dr. Hipkiss and what action, if any, can be taken thereupon.

Second, The Question of Fellowship in this Society, as embraced in Articles I. and II. of the By-Laws.

The desire having been expressed that the reports of the Committee on Medical Diplomas, which were adopted by the Councillors at their meeting, February 1st, should be printed in full, they are here given to the readers of the JOURNAL.

BOSTON, January 26, 1888.

The Committee on Diplomas would report in reference to the papers relative to Dr. George Hipkiss, which were referred to the Committee at the last meeting of the Council, that the By-Laws of the Society, as restricted in their application by a resolve passed by the Councillors, October 7th, 1874, with the concurrence of the Society, forbid the Censors from examining an applicant for admission to the Society who has received a degree of Doctor of Medicine from a Homeopathic College. No action can therefore be taken in the case of Dr. Hipkiss without a concurrent vote of the Council and the Society, and such an act of special legislation the Committee do not advise.

WM. L. RICHARDSON,
A. H. COWDEEN,
EDWARD J. FORSTER.

BOSTON, January 26, 1888.

The Committee on Diplomas, to whom was referred the question of Fellowship in this Society as embraced in Articles I. and II. of the By-Laws, would report that at present an applicant for admission to the Society must, among other qualifications, possess a diploma or its equivalent from an authorized medical school which is recognized by the Council. Having such credential he is obliged to pass an examination, a part of which must be in writing. Not possessing such diploma, or its equivalent, he cannot come up before the Censors for examination. The Council has adopted by vote a list of eighty-nine schools in this country whose diplomas shall be recognized. From the list are excluded all eclectic and homeopathic schools. A graduate therefore of an eclectic or homeopathic school, who becomes convinced by experience of the fallacious character of the tenets taught in those schools and who practises and believes as the members of this Society do, is not permitted to pass an examination before the Censors of this Society because he happens to be graduated from a school whose teachings, in a few respects only, we believe to be erroneous. In other words, the preliminary requisite for admission to-day, rest more on the diploma than on the knowledge, as shown by an examination, possessed by the applicant for admission. The Society would, in the opinion of the Com-

mittee, gain more if the diploma was considered of secondary importance, and the examination made the real test.

To prevent any misunderstanding and determine what schools should be recognized, the Council, October 7, 1874, and the Society, by its concurrent action the same day, voted:

That tickets or diplomas of Botanic, Eclectic or Homœopathic colleges, or of colleges devoted to any peculiar or exclusive system of medicine, are considered irregular, and will not be recognized under any circumstances;

And, That certificates from teachers, who practise any peculiar or exclusive system of medicine, who advertise, or who violate in any way the code of ethics adopted by the profession in this State, will not be taken, even though the teacher himself be a regular graduate in medicine.

It seems evident to the Committee that, without such a vote of restriction, the Council could, if they saw fit, recognize the diploma of any eclectic or homœopathic school as evidence of such an education as is required by By-Law I.

The Committee are of the opinion that the present policy of the Society is as illiberal as it is unjust and unwise. They believe that any physician apparently well educated should have the right, at least, to be examined as to his educational qualification in the branches specified in By-Law I. The education furnished by some of the eclectic and homœopathic schools in these branches is equal in its character and thoroughness to that furnished by many of the schools now recognized by the Council, and superior to some of them. The text-books used are, with few exceptions, identical. It does seem, therefore, unjust to require a graduate from these prescribed schools, without exception, to spend three years more in acquiring another diploma. Such a requirement must practically be a bar to admission to the Society. The Committee believe that a graduate from any school which the Council may recognize as furnishing the required education, and who proposes to renounce eclecticism, homœopathy or other exclusive dogma, should have the right to be examined for admission, and, having passed the required examination, should be admitted to the Society, fulfilling of course the other requirements for membership, as stated in the By-Laws.

It seems to the Committee that any well educated physician, whatever his previous belief or affiliations may have been, who renounces his past errors and wishes to adopt the truer and more rational practice of this Society should not be debarred by an iron rule, but rather welcomed and encouraged. Such liberality and wisdom of action on the part of the Society will commend itself not only to the profession at large, but to the community, and deprive the advocates of homœopathy and eclecticism of the role of martyr, which has done so much to promote and perpetuate homœopathy and eclecticism in this country. With this end in view the Committee recommend the repeal of the second and third paragraphs of the vote just read.

Should these paragraphs be repealed, the Committee will report at the next meeting of the Council the names of such eclectic and homœopathic schools as, in their opinion, furnish the required education, and which should therefore be recognized by the Council.

WM. L. RICHARDSON.

EDWARD J. FORSTER.

Correspondence.

DR. H. O. MARCY AND THE MURDOCK LIQUID FOOD HOSPITAL.

116 ROYALTON ST., BOSTON, February 15, 1888.

MR. EDITOR.—Permit me in favor of your columns to inform any interested that I am not connected with the Free Surgical Hospital for Women, supported by the Murdock Liquid Food Company. I gave much time without compensation to its organization, with the understanding that it should be a great charity, worthy of the approval of

the most critical, conducive alike to the relief of suffering and the proper teaching of Gynecology, both clinically and in journalistic form. Having failed to secure that which I thought the profession demanded, after consultation with eminent medical men, I felt it obligatory to withdraw last July.

Very respectfully,

HENRY O. MARCY, M.D.

SANITARY CONDITION OF WATERTOWN ARSENAL.

WATERTOWN ARSENAL,

WATERTOWN, MASS., February 13, 1888.

MR. EDITOR.—Your editorial on the required sanitary improvements at this arsenal, found in the number issued February 9th, does not do justice to Dr. Alfred Hosmer, late Post Surgeon here, who held that office for eight (8) years with entire satisfaction to the authorities; and it reflects injuriously upon the efficient Contract Surgeons at the Watervliet and Frankford Arsenals.

Without detracting from the merits of the present Post Surgeon, Dr. McKee, who has been active in the matter, it is due to Dr. Hosmer to say that it is through no fault or neglect of his that a better system of sewerage does not exist at this post. The original report on the subject was made by him, and he pointed out that while the sanitary condition of the post was now good, the existence of numerous open cesspools endangered it, and he made efforts to effect the improvements needed.

Respectfully, your obt. servant,

F. H. PARKER,

Lt.-Col. Ord. Dept. U.S.A., Commanding.

[The editorial in question recognized previous reports on the sanitary condition of the Watertown Arsenal. It had not occurred to us that it would be interpreted as reflecting upon the Contract Surgeons. We had in mind especially the dilatoriness of Congress, and the difficulty of procuring congressional action upon such a matter as this.—ED.]

THE NEED OF A NEW HOSPITAL AT RAINSFORD ISLAND.

BOSTON, February 19, 1888.

MR. EDITOR.—The Directors of Public Institutions, in their report of a year ago, asked for an appropriation for a new hospital at Rainsford Island, in Boston Harbor. The request attracted no particular attention, and was passed over by the City Government. The Directors now renew it, and speak of the need in strong terms. As I have been a member of the Board, and know from personal observation how crying the need is, I am anxious to add my testimony, in the hope of awakening the attention of the profession, and of the community in general to this matter, so that it may not be ignored a second time.

The institution at Rainsford is for male paupers. The chief building is fairly good, but the hospital is outrageously bad. It is one of the familiar landmarks of the outer harbor, a caricature of a Grecian temple. I do not know how long it has been used as a hospital, but, unless I am greatly mistaken, for upwards of thirty years. It is old, unventilated, dirty, crowded, and absolutely repulsive. I do not think I am using too strong language in calling it a disgrace to the city. I have not been inside the building for some two years, but I am credibly informed that it has not improved during that time. When I was on the Board an effort was made to remedy the over-crowding, but the gain was very great, and, I believe, not permanent. The building is so old and bad that any attempt at renovation would be a mere waste of money. A new building is needed. The Directors in their recent report speak plainly; but it is to be feared that if no general interest is taken in the matter they may again speak in vain. I am sure that if the public appreciate the state of affairs their

request will meet with the success it deserves. Common humanity demands better provision for the sick paupers.

THOMAS DWIGHT, M.D.

"FOURTH YEAR" GRADUATES HARVARD MEDICAL SCHOOL, 1886-87.

ALLSTON, February 18, 1888.

MR. EDITOR,—I notice in the *Boston Medical and Surgical Journal* of February 16th, on page 183, an editorial article entitled, "Annual Report of the Harvard Medical School, 1886-87," in which you state that the fourth year class of 1886-87 numbered twenty-one, that eleven of them applied for the degree, and that five received it.

I have before me the catalogues of the Medical School for that year, and also the last commencement programme, which contains a list of those upon whom degrees were conferred. I find on this programme, on page 6, the name of but one member of the above class, which seems to declare that he was the only one of that class on whom that degree was conferred.

I have a copy of the official report of examinations, as posted on the bulletin boards of the Medical School, which shows that but one man of the fourth year class, viz., No. 17, was properly entitled to the degree. How, then, can the president report that five received it? As I was the No. 17, you will pardon me for calling attention to this statement. It is not justice to me that such a misleading statement should be published in so accurate a paper as the *JOURNAL*, and I am sure that if those who spend four years in working for a special degree are not to receive due credit for their work, it cannot be expected that others will spend their time in a similar manner.

I do not know the five to whom reference is made, but I do know that only one from my class was properly entitled to the degree.

I trust that this correction will find a place in your next issue.

Very truly yours,

E. SCOTT DOW, M.D.

[*The ipsissima verba* of the President's report were given in our editorial. If there be any error it is his. There seems to be a confusion between the fourth year degree, and the same *cum laude*.—Ed.]

A CASE OF HÆMATURIA.

LOWELL, February 14, 1888.

MR. EDITOR,—A case of hæmaturia occurring in my practice may throw a little light on Dr. Benne's case, [*JOURNAL*, Feb. 9th, p. 148]. A man fifty years old came to me on account of finding blood in his urine. He had had the same trouble two years previous, and had been treated with ergot, tannic acid, etc., by our best practitioners without benefit. The first attack ended after a month's duration. The attack began four days before I saw him. Examination of the last urine showed nothing abnormal except blood and slight trace of albumen. Physical examination of patient negative. I concluded that the hæmaturia was functional, analogous to certain cases of nose-bleed, and decided to give him a general tonic and a renal stimulant. On the evening previous to his appointment with me he attended a Masonic supper, and took, contrary to custom, some rum pudding, which cured his hæmaturia completely, and prevented me from prescribing. He has remained well since.

Very truly yours,

J. ARTHUR GAGE, M.D.

Deaths reported 2,402; under five years of age 783; principal infectious diseases (small-pox, measles, diphtheria and croup, diarrheal diseases, whooping-cough, erysipelas and fevers) 277, acute lung diseases 425, consumption 285, diphtheria and croup 128, scarlet fever 42, diarrheal diseases 74, typhoid fever 23, measles 16, erysipelas 15, whooping-cough 14, cerebro-spinal meningitis 11, malarial fevers nine, small-pox (New York) one. From typhoid fever, Philadelphia 10, District of Columbia three, New York, Baltimore and Boston two each, New Orleans, Pittsburgh, Milwaukee and Nashville one each. From erysipelas, New York eight, Baltimore three, Boston two, Worcester and Lowell one each. From whooping-cough New York seven, Boston three, Philadelphia two, Baltimore and New Bedford one each. From measles District of Columbia seven, Baltimore four, New York three, Philadelphia and Lawrence one each. From cerebro-spinal meningitis, Worcester three, Philadelphia and Milwaukee two each, New York, District of Columbia, Lynn and Salem one each. From malarial fever, New York three, New Orleans two, Philadelphia and Charleston one each.

In 22 cities and greater towns of Massachusetts with an estimated population of 1,057,621, the total death-rate for the week was 22.50 against 25.16 and 23.87 for the previous two weeks.

In the 28 greater towns of England and Wales with an estimated population of 9,338,574, for the week ending January 28th, the death-rate was 22.5. Deaths reported 1,656; infants under one year of age 304; whooping-cough 214, scarlet fever 61, measles 47, diphtheria 46, fevers 39, diarrhoea 32, small-pox (Sheffield 37, Leeds and Bristol one each.) 39.

The death-rates ranged from 14.3 in Brighton to 31.9 in Manchester; Birmingham 23.5; Bradford 15.9; Hull 20.6; Leeds 21.1; Leicester 21.7; Liverpool 21.1; London 22.1; Newcastle-on-Tyne 21.7; Nottingham 21.0; Sheffield 26.4; Sunderland 20.2. In Edinburgh 22.4; Glasgow 23.2; Dublin 33.1.

The meteorological record for the week ending February 11, in Boston, was as follows, according to observations furnished by Sergeant O. B. Cole, of the United States Signal Corps:—

ARTHUR, WM. H., captain and assistant surgeon. Leave of absence extended two months. S. O. 35, A. G. O., February 13, 1888.

JARVIS, NATHAN S., first lieutenant and assistant surgeon. Ordered from Fort Lewis, Colorado, to Fort Leavenworth, Kansas. S. O. 39, A. G. O., February 7, 1888.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE UNITED STATES NAVY DURING THE WEEK ENDING FEBRUARY 18, 1888.

OLcott, F. W., assistant surgeon. Detached from the "Minnesota" and to the "Atlanta."

HAYL, T. C., surgeon. Ordered to the receiving-ship "St. Louis."

MARTIN, H. M., surgeon. Detached from "St. Louis" and to the "Swatara."

WEISTER, CHAS. F., assistant surgeon. Ordered to the receiving-ship "Vermont."

FIELD, JAMES G., assistant surgeon. Detached from the "Vermont" and to the "Swatara."

WHITING, ROBERT, passed assistant surgeon. Detached from the "Iroquois" and to the Coast survey.

TEAM, ELOHSE C., assistant surgeon. Resigned, to take effect immediately.

SOCIETY NOTICES.

AMERICAN MEDICAL ASSOCIATION. The Thirty-ninth Annual Session will be held in Cincinnati, Ohio, on Tuesday, Wednesday, Thursday and Friday, May 8th, 9th, 10th and 11th, commencing on Tuesday, at 11 A.M. A member desiring to read a paper before a Section should forward the paper, or its title and length (not to exceed twenty minutes in reading), to the Chairman of the Committee of Arrangements at least one month before the meeting. Committee of Arrangements, W. W. Dawson, Cincinnati, Ohio, Chairman.

WM. B. ALKESON, M.D., Permanent Secretary, 1400 Pine Street, Philadelphia.

NORFOLK DISTRICT MEDICAL SOCIETY.—A meeting for Scientific Improvement will be held at the Hall of the Roxbury City Guard, 67 Warren Street, Roxbury, February 28, 1888, at 7.45 P.M. Communications: 1. "Syphilis as a Cause of General Paralysis," Walter Channing, M.D. 2. "Syphilis and Marriage," James C. D. Pigeon, M.D. 3. "Pathological Specimens," W. P. Holmes, M.D. S. A. Potter, M.D. Dr. H. R. Stedman is expected to open the discussion of the first subject.

S. ALLEN POTTER, M.D., Secretary.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.—A Regular meeting of the Society will be held Monday, February 27, 1888, at the Medical Library, 19 Boylston Place, at quarter of eight, P.M. Dr. A. T. Cabot will show "A Series of Cases of Excision of the Ankle." Reader: Dr. Charles Harrington. Subject, "The Value of So-called Diabetic Foods."

F. E. HARRINGTON, Secretary.

DEATH.

Died in Cambridgeport, Mass., February 17, 1888, Charles Derwick Wellington, M.D., M.M.S.S., aged twenty-eight years.

POSTERO LATERAL SPINAL SCLEROSIS [GENERIC ORIGIN]; OR GENERIC ATAXIA.

A NAME SUGGESTED IN PLACE OF HEREDITARY ATAXIA OR FRIEDREICH'S DISEASE.¹

BY W. EVERETT SMITH, A.B., M.D., BOSTON, MASS.

The great desideratum in nomenclature as applied to diseases is that the name of each disease shall express the morbid condition involved and its situation. — *Flint's Practice of Medicine*.

Scientific nomenclature should be itself scientific, not founded upon accidents. However anxious we may be to honor individuals, we have no right to do so at the expense of the convenience of all future generations of learners. — *Gowers: Diagnosis of Diseases of the Spinal Cord*.

THE system of naming diseases after individuals or symptoms possesses so few advantages and leads to such misunderstandings and confusion in diagnosis that it cannot upon any ground be commended. How many general practitioners recognize, for example, in the columns of Türok, the anterior pyramidal tracts of the spinal cord, or in the columns of Goll, the postero median columns, or in the columns of Burdach, the postero external columns or under the name of the Romberg symptoms, the well-known inability of an ataxic person to stand without staggering when the eyes are closed? So too the disease first described by Friedreich and commonly called Hereditary Ataxia has been so little understood and so often confounded with the more common and pathologically speaking, less complex disease, locomotor ataxia, that I cannot help feeling that much of this inaccuracy and confusion is due simply to a faulty nomenclature.

A brief sketch of this nomenclature may prove instructive. Friedreich observing two ataxies in one family and four in another which seemed to him to present symptoms radically different from those ordinarily classed under the name of locomotor ataxia, reported them in 1861 before the forty-second meeting of German naturalists and physicians held at Spire but did not publish them until 1863. He classified them simply as degenerative atrophy of the posterior spinal columns. Meanwhile, however, Carre in Paris had published a record of seven cases of ataxia in a single family under the common, but in his cases particularly vicious, name of "progressive locomotor ataxia." And yet I grant there may seem to be some excuse for his term, since with a stronger element of direct heredity than have any other recorded ataxic cases, his patients unquestionably combined some of the classic symptoms of the ordinary locomotor ataxia. Following Carre came Topinard in 1864, Carpenter in 1871, Kellogg in 1875, and D'Arcy Power in 1882, all reporting family groups of ataxic cases under the names of locomotor ataxia and hereditary locomotor ataxia.

In 1882, also, Dr. William A. Hammond reported under the title hereditary locomotor ataxia, six cases, two in one family and four in another, which, however, instead of presenting symptoms of ataxia, as one might suppose from the title of the paper, presented no incoördination at all but only loss of motion in the legs. In commenting also upon Friedreich's cases, he says, "the first symptom observed was weakness of the lower extremities, and this gradually extended so as to involve the upper extremities. Here was, there-

fore, a true paralysis." This I take to be an entire misinterpretation of Friedreich's cases, so that while there may be good reasons for the conclusion that Friedreich's cases were not locomotor ataxia, I fail to see why Hammond's cases should be classed as ataxies of any form since in no instance are they recorded as presenting the slightest trace of any incoördination of movement.

Now although it is true, as Ormerod has said, that there have been cases of Friedreich's disease, so-called, where paralysis of the lower limbs has been reported, "in no case has it been observed until the disease had existed for a period of years, and in some very carefully observed cases there has been no paresthesia at all, but simply ataxia. Again, although in some cases diminution of sensibility has been noted, it is usually for the earlier periods, in quite an insignificant degree, and in many cases every abnormality of sensation has been thoroughly excluded. We have, therefore, in this disease an illustration of ataxia pure and simple, apart from motor or sensory paralysis."

Clinically speaking, the difference between the classic locomotor ataxia and the so-called hereditary ataxia may be distinctively arranged into three general groups. In the first place, ordinary tabes does not run in family groups, while Friedreich's disease clearly does. Yet the cases are few where, even in the latter disease, a strict heredity can be claimed. It attacks, as a rule, members of the same generation in the same family, although occasionally successive, as well as simultaneous, outbreaks have been observed in the same family, as, for example, in Carre's cases, where the mother of the seven ataxic patients, her brothers and sisters to the number of eight, and her mother were all ataxic; in Brousse's case, where the mother was ataxic; in one of Rüttemeyer's cases, where a male ancestor five generations back was ataxic; and in my series of cases,² where the father of the five affected girls clearly developed the disease late in life. More often, however, a remarkable proclivity to other forms of disease has been observed in these family forms of ataxia: "on the side of the nervous system, to chorea, paralysis, hysteria, mental affections, intemperance; on the side of general diseases, to phthisis."

Secondly, ordinary tabes is a disease of middle age or of later life, while the family form of ataxia develops usually in early childhood. Friedreich held that its development was connected with the changes of puberty, and that females were particularly prone to it; while Ormerod believes that the onset of an acute disease may have a possible influence in its production. The disease is unquestionably due to a lack of proper development of the nervous elements of the cord and their consequent atrophy, and it is worthy of notice that the ataxic families are generally large, so that it may be that the rapid production of children may have caused an imperfect development of some of them. At any rate, enough cases have now been reported to show that sex has nothing to do with either the development or the occurrence of the disease.

Nor do I believe that puberty is a potent or a common cause.³ The majority of cases thus far reported began to show an evident lack of development at as early an age as five or seven years, and I very much

¹ Suggested by the writer at a meeting of the College of Physicians, Philadelphia, February 1, 1888, which he attended by the invitation of Prof. Wm. Osier.

² Boston Med. and Sur. Journal, October 15, 1885, p. 361.

³ Boston Med. and Sur. Journal, February 16, 1888, p. 175.

suspect that if these cases had been more carefully watched, they would be found never to have been as steady in their movements as were other children. At the age, however, when they would naturally begin to romp and run, the parents may possibly observe that they cannot carry themselves as well as their playmates can, but, think little of it perhaps, until the onset of an acute disease, or the extra demands which puberty makes upon the system has allowed the incoordination to develop to such an extent that it can no longer be unnoticed.

Thirdly, the absence of sensory derangements in the hereditary forms of ataxia is of great diagnostic value. In typical tabes, as is well known, the lancinating pains are usually a prominent symptom, especially in the early stages, and are rarely absent throughout the entire history of the disease, while other sensory disturbances, such as numbness and local anæsthesia, frequently accompany the incoordination of movement. But in the majority of cases of family or 'hereditary' ataxia pain is conspicuous by its absence, until at least, the disease is very far advanced, although it is true that cases have been observed, such as those of Carre and Dreshfeld, where it occurred as an initial symptom. The absence of the knee-jerk is, indeed, common to both of the forms of ataxia which we are discussing, but the curvature of the spinal column, which occurs so early and so markedly in the family form of the disease, does not belong to the history of locomotor ataxia. Another critical diagnostic symptom is the affection of the speech in the hereditary form of ataxia. "From a mere drawl, stammer, undue confluence, or undue separation of syllables, the affection may advance till speech becomes wholly unintelligible."

The highest level to which the hereditary disease extends is marked in its clinical aspect by the symptom of nystagmus. Bilateral and transverse in its action, it is observed only when the patient looks at or follows an object intently. Being a very late symptom, its absence in a given case need not tell necessarily against the diagnosis of the family form of the disease. Bed-sores and visceral disturbances never occur, as they so commonly do in locomotor ataxia.

Seeing, then, how marked the contrast is between the two diseases, it is not in the least surprising that some authors should have denied altogether the existence of relationship between them. Thus, on the one hand, Hammond maintains that Friedreich's cases are not examples of primary disease of the cord at all, but of disease of the medulla or cerebellum, extending secondarily to the cord; while, on the other hand, Vulpian, Charcot, and Bourneville regard them to be simply a variety of disseminated sclerosis. Although the affection of speech and the nystagmus would seem to lend some plausibility to the latter theory, the morbid anatomy of the cases, as revealed by autopsies, must be our final test, and by this we find conclusively that the disease is spinal, and not cerebral, in its origin; that whatever cerebral degeneration there is, is late and entirely secondary in its development; and that, moreover, the spinal sclerosis is systematic, and not disseminated, in its character.

Nor does the suggestion of Erb that cases of tabes may be grouped under two types, the classical type and the type described by Friedreich, seem entirely appropriate when we come to look at the pathology,

although the occurrence of forms apparently transitional between the two, may give some reasonable support to the idea. Such cases are those reported by Carre, where there was a well-marked affection of the speech, and a distinct heredity, yet where the disease began with pains and numbness in the legs and feet, and those reported by Dreshfeld where there were pains from the onset, and no affection of the speech reported. In three of Friedreich's own cases, also, these early pains were noticed, and in Powers' case there appear to have been vomitings at an early period. Other aberrant forms are the two cases of Seeligmüller which Friedreich refused to recognize as of the same type as his own cases, chiefly because of some mental peculiarities and the persistence of the knee-jerk.

The disease first described by Friedreich does indeed differ so materially from the classic locomotor ataxia as to deserve and demand a separate classification and a distinctive name, but as it seems to me, not in the manner I have just outlined. The autopsies which have been made are unfortunately few. Deaths have occurred as a rule from some intercurrent disease and rarely, if ever, in the early stages of the spinal degeneration. Our pathological knowledge therefore rests entirely upon eleven post-mortem examinations (Friedreich, four; Schnltze, one; Kahler and Pick, one; Brousse, one; W. E. Smith, one; Gowers, one; Rüttemeyer, two; but these fortunately agree in the main upon several essential points.

In all of them there has been found an atrophy and degeneration of nerve-fibres throughout the entire length of the posterior columns, especially in the dorsal and lumbar regions, a similar, although less marked process in the lateral columns, affecting the periphery of the cord in the lumbar region chiefly, together with a degeneration, to a certain varying extent, of the anterior columns in the neighborhood of the median fissure in the cervical and dorsal regions. The posterior nerve-roots were also diseased but the anterior were relatively healthy. The meningeal mantle of the cord was somewhat thickened and the cord itself diminished in size. In Brousse's case and in my own, there was a well-marked inflammation of the central canal which was full of small, deeply-staining cells. Upon this Brousse lays great stress, considering that by this means, the disease spreads from the posterior columns to the other parts of the cord. He holds that the sclerosis of the posterior columns is primary and systematic, while the sclerosis in other parts is secondary to it and diffuse, that is, not limited to nor propagated along particular tracts of fibres.

A careful study of the cord will, I think, convince every one that the sclerosis of the posterior columns is indeed primary, while that of the lateral and anterior columns is secondary to it. But I cannot grant that this secondary degeneration is diffuse in its character. On the contrary, in all the sections which I have examined from this disease, the degeneration is clearly limited to and propagated along definite, systematic tracts of fibres.

To settle the point decisively whether the spread of the degeneration has taken place by simple contiguity, by meningitis, or by the medium of an inflammation extending along the central canal, we need, as Ormerod suggests, further examinations, and especially examinations at early stages of the disease. My opinion is, however, that it extends by means of a meningitis.

We have seen that the disease under consideration occurs distinctively in family groups, yet is rarely hereditary in the strict acceptance of the term, and we have studied its accurately-determined clinical and its fixed pathological peculiarities. We have seen, too, that the names commonly applied to the rare affection are both confusing to exact diagnosis and undesirable as scientific terms. The disease may, however, be fairly and distinctively represented by the degenerations which occur in the posterior and the lateral columns. The name I therefore present for consideration as an exact, pathological and altogether more appropriate one than any of the names now commonly applied to the disease, is "Postero Lateral Spinal Sclerosis of Generic Origin." With such a nomenclature as this, we can clearly and intelligently contrast and compare the disease both with posterior spinal sclerosis (locomotor ataxia), and with other forms of spinal degeneration. As a colloquial term for ordinary use, moreover, I would suggest "Generic Ataxia." And I have chosen the name "Generic" because it seems to me to convey fully the idea of a family grouping, and if we please, family transmission, without involving the vexed question of a strict inheritance from ancestor to descendant. The term "Sclerosis" I adopt, it should be said, under a mild protest, since it does not seem to me an altogether happy term. Its rejection, however, would involve a complete revision of the accepted scientific nomenclature of nervous diseases.

THE VALUE OF WALL-PAPER GUARANTEES.

BY CHARLES HARRINGTON, M.D.,
Instructor in Hygiene and Assistant in Chemistry in the Harvard Medical School.

In the discussion of a recent report of a case of poisoning from arsenical wall paper read by Dr. W. E. Smith before one of the sections of the Suffolk District Medical Society, the question was asked as to "what degree of reliability may be placed on the testimony of paper manufacturers, or dealers, as to the absence of arsenic in their manufactured fabrics." To this question it may be answered that the degree of reliability of such testimony depends greatly upon the character of the person or firm giving it, upon the character and ability of the chemists employed for the analysis, and upon the amount of mental reservation which may be made at the time of sale. There are business houses in this city which, when requested, and frequently without solicitation, give an absolute guarantee that the papers sold are either strictly non-arsenical, or contain insignificant, harmless traces. These houses, as a rule, employ competent, reputable chemists, upon whom the responsibility for the accuracy of the analysis rests. There are others who give their patrons, in place of a guarantee, a statement that their goods are all examined by their chemists, and are perfectly safe; the value of which statement is not clearly perceptible.

Some dealers when asked for a guarantee, reply that the papers are guaranteed by the manufacturers, which statement is usually sufficient to relieve the intending purchaser of all doubt. When, however, after some time, symptoms attributable to arsenical poisoning appear, and the papers are found to be highly arsenical, and the innocent purchaser demands redress of the dealer, he is very likely to be informed that

the papers were guaranteed, not by the dealer himself, but by the manufacturer, to whom (in another State, or in a foreign country) the victim must apply. There are others who treat inquiries as to safety with withering contempt, descent upon cranks and other offensive persons, show themselves as lusty specimens of manhood brought up in the business, handling the alleged poison day in and day out without the slightest injury, and frighten their customers, who may not wish to be considered imbeciles into buying without a guarantee of any sort.

But even the honestly made guarantee of a reputable dealer is not always safe from a sanitary, though perfectly so from a pecuniary point of view. It has happened not infrequently in the experience of several of our most reputable dealers, that they have been obliged to suffer extensive pecuniary loss in replacing papers sold on the certificates of incompetent chemists. In fact, one of these dealers informed the writer that the worthless certificates of a certain chemist had cost him more than five hundred dollars in a single house.

But what about the "manufacturers' guarantees," about which one hears so much? It is perfectly obvious that to the individual purchasing through a retailer such guarantees are hardly worth the effort of demanding them. But, it may be said, the dealer may demand a guarantee of the manufacturer, and then give his own to the customer. This is precisely what is done in certain cases, and not always with advantage to the dealer; for, having given his personal guarantee, he is bound for the sake of his own reputation for honest dealing, if indeed for no other reason, to make good any loss to the customer, while at the same time he may be left in the lurch by the manufacturer, who may refuse to accept any certificate of analysis presented by the dealer, or meet the same with another of different, and it is needless to say, more favorable import. Illustrative of this point the following case may be related: Some months ago a well-known house in this city, with a reputation for fair dealing, imported from England under a "manufacturer's guarantee" a large lot of expensive papers, samples of which, on the arrival of the goods, were submitted to the writer for analysis, with the result that eight of the papers were condemned. Upon this the manufacturers were notified that the paper must be taken back; but they were equal to the emergency, as the following letters will show. The names of the dealers on both sides are suppressed for obvious reasons.

LONDON, S.W., May 25, 1887.

Messrs. ———, Boston, America.

Dear Sirs, — Since writing you on the 5th inst., we have submitted the eight samples of wall-papers that you describe as arsenical to Prof. John Atfield, one of the highest authorities as a practical chemist in London (who has preserved the test-tubes), and he pronounces each to be free. We send copy of his report. Professor Atfield is the chemist employed by Messrs. ———, and his examinations may be considered as perfectly reliable. . . . Our colors are bought under a guarantee, and the red color of which you complain was manufactured by Lewis Berger Sons, Ltd., under a guarantee. We thoroughly believe that these papers are non-arsenical in the ordinary sense of the term.

We trust, under the circumstances, you will have every confidence in the goods, and find a ready sale for them.

We remain, yours respectfully, ———

The report on the eight samples which accompanied the above was as follows:

REPORT OF AN ANALYTICAL EXAMINATION FOR ARSENIC, IN EIGHT SAMPLES OF MESSRS. WALL-PAPERS.

BY PROFESSOR ATTFIELD, PH.D., F.R.S., F.I.C., F.C.S.,

Professor of Practical Chemistry to the Pharmaceutical Society of Great Britain, Author of a Manual of Chemistry and a Handbook on Water Supplies, etc.

LONDON, 17 Bloomsbury Square, W.C.,
May 13, 1887.

The samples were marked as follows: Iberia, 60,500; Monkshood, 60,334; Coniston, blue, 60,474; Wentworth, on white, 58,572; Wentworth, on yellow, 58,572; Brandon, 60,063; Chatsworth tale, 60,156; Malines, 60,144.

Not one of these samples is an arsenical wall-paper: that is to say, not one of the pigments or color-giving substances on the papers is arsenical, and the paper itself of these paper-hangings is not arsenical.

Pseudo-sanitarians sometimes report non-arsenical wall-papers as containing some ridiculously minute trace of arsenic. These alarmists might just as truly report some samples of common table salt as containing arsenic, for the delicacy of certain of the tests for arsenic is so great that traces can be detected in many things. But such traces are absolutely without significance from any sanitary point of view, either in salt, wall-paper, or anything else. Arsenical wall-papers have well-defined arsenical characters, were formerly common, and may now occasionally be met with. Neither of these samples is an arsenical wall paper.

(Signed) JOHN ATTFIELD.

Accompanying this report was a printed circular setting forth that "every care is taken to produce papers that are quite free from injurious compounds," etc., etc., and containing copies of reports by "two eminent authorities" that certain papers, including some of the above mentioned, are free from arsenic.

The letter, accompanied by such a report from so distinguished an authority, could not but have a deterring influence on the Boston house. But in spite of the warning against the baleful influence of all pseudo-sanitarians and alarmists, the papers were again submitted for analysis, and again were they condemned. The condemnation, on the one hand, and the refusal to receive the papers back on the other, left the dealers but one course to pursue, and that was to sell the papers as arsenical. So much for the value of a "manufacturers' guarantee."

The remarks concerning pseudo-sanitarians made by the distinguished London chemist in his report show that the English conception of pseudo-sanitarians is somewhat different from ours. Our pseudo-sanitarian is prone to find no arsenic where it may exist, though he may, if reasonably skilful and employing pure chemicals, find it where it is not. But with absolutely pure chemicals and clean apparatus it would be extremely difficult, and indeed impossible, to detect even traces of the poison in substances where it does not exist, no matter how much of a pseudo-sanitarian one may be. In order to clear up the matter of accuracy, the writer forwarded samples of the papers in question to Professor Henry B. Hill, Professor of Chemistry, Harvard College, Cambridge, and to Dr. Charles R. Sanger, Professor of Chemistry in the United States Naval Academy, at Annapolis, Maryland, with requests for quantitative estimation of the arsenic, if any were found to be present; at the same time undertaking the same estimation himself. In their reports to him the writer is informed that

none but absolutely pure chemicals were used, and that blank experiments with the apparatus used resulted in blank results. In the following table may be seen the results of all the chemists concerned:

Name of Paper.	Manufacturer's No.	Amount of Arsenic in grs. per sq. yd.			
		Hill	Sanger	Harrington	Attfield
Chatsworth tale	60,156	4.66	4.68	4.40	0.00
Brandon	60,063	0.85	0.73	0.90	0.00
Malines	60,144	0.93	0.73	0.82	0.00
Iberia	60,500	0.63	0.71	0.78	0.00
Coniston, blue	60,474	0.21	0.23	0.18	0.00
Monkshood	60,334	0.12	0.04	0.14	0.00
Wentworth, on white	58,172	0.10	0.08	0.13	0.00
Wentworth, on yellow	58,172	0.21	0.22	0.22	0.00

It is, it must be conceded, somewhat remarkable if the papers are non-arsenical that the results of the three American chemists should bear such a close resemblance. The results are not in absolute agreement, it is true, but the slight differences are doubtless due in part to the fact that the papers are figured, and in part to the universally recognized possibility of chemical fallibility.

It is interesting to note that all of these papers contain more than the permissible limit recommended to the National Health Society of England by its committee, which was composed of men whom we in America recognize as true sanitarians — Professor F. de Chantmont, H. C. Bartlett, and Charles Heisch.

What is the value of a guarantee? The writer trusts that it has been made clear that it depends upon the guarantor.

ANTISEPTIC MIDWIFERY.¹

BY H. F. ADAMS, M.D., NEWBURYPORT, MASS.

THE recent progress of medical knowledge towards that precision and completeness which shall justify the term scientific medicine, has in no direction been more encouraging than in that of the study of bacteriology.

No more promising field has ever been entered, and now, even in the infancy of the study, the results are brilliantly successful. At last we can see, in some diseases at least, the mysterious and dreaded primary cause of the pathological changes which we seek to cure.

A most remarkable illustration of the fact that practical results must follow the modern keen and searching investigation into this formerly hidden department of natural history, is presented to us in the now generally accepted views regarding puerperal septicæmia, its prophylaxis and its treatment.

The old puzzle of puerperal or child-bed fever is now solved. Only a very small and constantly diminishing number of obstetric authorities still refuse to believe that this fearful scourge of the past, second in its deadliness, among women of the child-bearing age, only to tuberculosis, is simply septicæmia, attacking the wounded lacerated parturient, as it does the surgeon's patient, solely through local infection from external sources of contagion.

Forty years ago, Semmelweis, of Vienna, after magnificent reasoning upon facts under his keen and close observation, proclaimed the absorption of septic

¹Read before the Essex North District Medical Society, January 4, 1888.

matter to be the cause of this disease. His conclusions, ridiculed and rejected then, only needed the light of the bacteriological knowledge of this later day to force acceptance.

The ideas of medical men regarding puerperal fever have been very varied and very vague. Physicians who have often seen, in their practice, severe "milk fevers," "milk legs," lymphadenitis, cellulitis, metritis, peritonitis, abscesses, pericarditis or similar inflammatory febrile complications of the puerperal state, have gravely stated that they never met with puerperal septicæmia. Often, indeed, has the nature of child-bed fevers been entirely overlooked, and some typhoidal state, or nervous condition, or malarial poisoning, or exposure to cold, been considered the cause of the sad results.

But at last the light has come. The reason for the terrible mortality from these mysterious and dreaded fevers has been discovered. And better still, with the new knowledge has come the successful method of prevention; a simple means by which such fearful records are now matters only of history.

The investigations of Pasteur into microbic life, and the consequent reform in surgery based upon the views and practice of Lister, inspired in obstetricians, who accepted the teachings of Semmelweis, earnest endeavors to secure similar prophylaxis in midwifery. So slow has been the progress that many have doubted the soundness of the new theories. Discussions upon the nature of puerperal fever, like the one in the Obstetrical Society of London, in 1875, have shown great diversity of belief, and many of our text-books yet teach in a guarded and even doubtful way. Practical efficacy has constantly arisen from the inefficiency or harmfulness of antiseptic measures used, and for a time the results, though encouraging, were after all, only indifferently successful.

The investigations of Dr. Robert Koch in 1879-80, upon bacteria and germicides, are to be remembered as a most important advance. From that time carbolic acid, then generally used in obstetric practice both in Europe and America, has been gradually superseded by the more powerful and convenient antiseptic, bichloride of mercury. And the methods of its use have been much improved, under the stimulus furnished by that concise knowledge of the parasitic or germ origin of this disease, for which, also, we are largely indebted to the same eminent Dr. Koch.

What particular variety, or varieties, of bacteria are the dangerous ones, we do not yet definitely know. But that some form of microbe is responsible, no longer admits of doubt.

Dr. H. C. Ernst, instructor in bacteriology at the Harvard Medical School, has furnished a clear statement of our present knowledge, for a paper by Dr. William L. Richardson, professor of obstetrics in the Harvard Medical School, published in the *Boston Medical and Surgical Journal*, for January 27, 1887. I quote a few selected sentences:

"A woman passing through the puerperal state with no untoward symptoms, has never been found to have bacteria in the system, whilst those attacked by 'puerperal fever' are invariably found to have bacteria in the tissues, bloodvessels or lymphatics of the affected part." . . . "The vagina contains bacteria in health, like the mouth, and like the bacteria in the mouth, those in the vagina do no harm." . . . "It is only by the entrance of pathogenic bacteria that a dis-

turbance is produced." . . . "The first condition necessary for the hurtful activity of bacteria to become manifest, is that there should be a solution of continuity, a wound of the skin or mucous membrane." . . . "The bacteria make their way in from outside. They are not born from nothing in the uterine tissues. There is no spontaneous generation about it." . . . "The problem is unquestionably how to keep the bacteria out of the body. Without them there will be no puerperal fever or septicæmia."

This statement, defining the positive knowledge of to-day, and not based upon theories simply, is worthy of thorough comprehension, and vivid remembrance. A complete acceptance of its teaching, aided by the powerful stimulus given by the fearful history of puerperal fever in the past, must give to every physician a lively sense of personal responsibility in the care of all confinements. Viewed from this position, how easy it is to see the origin of the deadly poisoning in cases previously inexplicable. The lacerated surfaces of the uterus and vagina after parturition present wounds typically dangerous for harmful absorption. Retained blood-clots, fragments of placenta or injured and dying tissue, furnish the best of soil for the propagation of septic germs.

Some unobserved collections of dirt, in creases of the skin or under the finger-nails of the physician or nurse, or upon the instruments or towels used, harbor the invisible bacteria. These become dissolved off during some slight manipulation, and the inoculation is done. Or perhaps the faithful efforts of the nurse to secure cleanliness, by bathing the patient's genitals with a common sponge or by giving vaginal douches with an apparently clean syringe, serve to communicate the subtle germs to the soil so especially adapted to their growth in rapidly spreading colonies.

Strict methods for preventing such infection are now almost universal in the Maternities abroad.

To Paul Bar, of Paris, is due much credit for the development of the technique of protection. A translation of his work, "Antiseptic Methods in Obstetrics," was published in Philadelphia in 1887.

In this country, great success has followed the adoption of these measures in the lying-in hospitals of our medical centres. In New York, Dr. H. J. Garrigue, in October, 1883, introduced the present method in the New York Maternity, and the mortality from septicæmia fell at once from over 6% for the preceding year to 0.59%. And for the following years, 1885 and 1886, it was only 0.02%. He has published explicit details in a small hand-book on "Antiseptic Midwifery." Lusk, in his classical work on midwifery, states that since adopting efficient antiseptics in the New York Emergency Hospital in 1883, there has been no death from sepsis up to the date of his last edition, May, 1885. Also, there has been a nearly uniform absence of even trivial temperature variations. He, in common with other antiseptists, now considers the so-called "milk fever" pathological and of septic origin. Dr. Robert Kucher, of New York, published, in 1886, a valuable work entitled "Puerperal Convalescence and the Diseases of the Puerperal Period," in which he treats ably of the principles and practice of antiseptic midwifery, his views growing largely out of the accepted practice of the Vienna Lying-in Hospital.

In Boston, in October, 1885, Dr. William L. Richardson, in the Boston Lying-in Hospital, introduced

practically the same measures as those so successfully used by Garrigues. The results are shown best by these charts, from the paper by him, already referred to.² The mortality for the year 1886 from septic diseases was nothing.

In Philadelphia, Dr. B. C. Hirst, although omitting the pad, is carrying out essentially the same antiseptic plan, in the Maternity Hospital. From May, 1885, to May, 1887, there was only one death from septicaemia, and this occurred before the thorough adoption of the system now in use.

Facts like these, from such authorities, justify the statement that confinement is now less dangerous to the diseased and miserable women of our charity hospitals, under strict antiseptics, than to healthy patients supplied with luxuries in comfortable homes, if treated upon the old plan. To appreciate something of the greatness of the advance, it is only necessary to compare the percentages of mortality just given with those of earlier years. Playfair says that in London, in 1760, 1768, and 1770, in some lying-in institutions, nearly all the patients died. In the Edinburgh Infirmary, in 1773, "almost every woman was seized with it, and all of them died." In Paris, Berlin, and Vienna, periods of a year at various times in the first half of the present century, gave mortality records, in hospitals, of more than 15%.

When Semmelweis announced the true nature of puerperal fever in 1847, the mortality in the Vienna Hospital was seldom less than 10%. Nearly twenty years later, the elegant Lariboisiere Hospital in Paris, while new, had an average mortality of almost 8%. At the same time, in the Paris Maternity, it was 10% for a period of nine years. For the following nine years, under Tarnier's efforts by the use of antiseptics, it fell in this same institution to 3.7%. To-day, in Germany and France, the mortality in hospitals is only a fraction of one per cent.

The method of application of the principles of antiseptics to the conduct of labor is really very simple, as carried out by leading obstetricians to-day. Good ventilation is, of course, insisted upon. Thorough cleanliness of the room, bed, and all attendants, is important. In hospitals and in private practice among the lower classes, the patient should be given a preliminary full bath. The rectum should be emptied by an enema of soap-suds. The external genitals, genito-femoral grooves and anal folds, thighs, and lower abdomen, are to be carefully washed with a solution of bichloride of mercury in water, strength 1-1000. This solution is most conveniently made by carrying in the obstetric bag a box of powders, each containing 1 gm., or gr. xv, of corrosive sublimate, and dissolving one of these in one litre, or one quart, of hot water. The hands of both physician and nurse must be thoroughly scrubbed with plenty of soap, using a stiff brush about the nails and the creases of the skin. When apparently perfectly clean, they must be washed, or soaked, in the above solution for, at least, one minute. This use of the disinfectant must be repeated previous to every examination or manipulation in the genital region. If instruments are called for, they are best cleansed in a saturated or five per cent. solution of carbolic acid just before use. The mercury solution corrodes and injures them. For lubrication of hands or instruments, an ointment composed of one part oil of eucalyptus, and seven

parts vaseline, is recommended by Dr. Richardson. Dr. Garrigues uses nothing at all, except when introducing the whole hand or using instruments. For these he recommends glycerine, with three per cent. of carbolic acid.

During the first stage of labor, before making any digital examination, the vagina should be thoroughly disinfected by an injection of the corrosive sublimate solution, diluted to 1-3000. About three pints is a proper quantity. It should be given upon the back, in order to distend the folds of the vagina, and to reach, thoroughly, the upper parts. It is well to have the patient sit up or turn upon the side immediately afterwards, so that no quantity may be retained in the vaginal pouch. If the labor is prompt and perfectly natural, no further injection is needed; but if the first stage is very much delayed, the douche should be repeated from time to time, in order to secure asepsis of the canal during the second and third stages of labor.

During the second stage, the external genitals and region about should be kept perfectly clean; all blood, urine, or fecal matter being carefully removed by means of pieces of absorbent cotton or charpie dipped in the prepared solution. The removal of the placenta should be by Credé's method, more than usual pains being taken to avoid unnecessarily passing the hand or fingers into the vagina. It is of great importance to secure subsequent firm uterine contraction. After delivery is complete, the woman is to be thoroughly cleansed externally, using the disinfectant. Any perineal rupture should be sought and closed at once with antiseptic sutures. No post-partum injections are advised, except after instrumental or manual interference. In such cases, as an additional safeguard, a vaginal douche may be rapidly given. If fœtus or placenta be decomposed or offensive, an intra-uterine injection is necessary. For these uses, a weaker solution, 1-4000 or 1-5000 will prove sufficient. Stronger solutions have caused poisoning, being absorbed by the fresh vaginal lacerations. It is desirable to wash out the last of the corrosive sublimate by a small quantity of two per cent. carbolic acid solution.

There has been some difference of opinion as to the best plan of dressing the external genitals after labor. Some advise and use nothing whatever, simply spreading disinfected cloths underneath to absorb the lochial discharge.

But the latest and best method is the use of the occlusion dressing, or the antiseptic pad. The object of this is to seal the entrance to the vagina and uterus, by a germ-proof protective, against the attacks of septic bacteria from the air or other external objects.³ These pads are found by experience to be easily prepared and not very expensive. They give the greatest comfort to the patient from their warmth, softness, cleanliness, and support, and they absolutely prevent all disagreeable odor.

It is now generally believed that all danger from septic diseases, contagious diseases, autopsies, etc., occurring in the physician's practice, may be removed by sufficient thoroughness in disinfection of the person, clothing, and other carriers of infection, previous to entering the lying-in room. Many conscientious practitioners have, for a long time, felt bound to

² See Boston Medical and Surgical Journal, January 27, 1887.

³ For the method of making and using the pad, see Journal, Vol. CXVI, p. 76.

decline all midwifery practice during attendance upon cases of erysipelas, scarlatina, diphtheria, typhoid fever, etc. The masterly pioneer work done by Dr. Oliver Wendell Holmes in 1843, in his paper, "Puerperal Fever a Private Pestilence," proved too convincing for their peace of mind when any fever among their patients followed disregard of his wise caution. If for no other reason than the safeguard it offers against the annoyance and anxiety caused by these dangers, which exist in every physician's practice, we should welcome the new method.

The measures best adapted to destroy the septic germs, when once they have unfortunately gained a foothold during the puerperium, I have not time to discuss. But for treatment of cases of puerperal septicæmia demanding intra-uterine disinfection, I wish to call special attention to a new method free from the dangers of injection of liquids, and apparently much more effective. I refer to the use of Ehren-dorfer's pencils of iodoform, described and recommended in the last edition of Lusk. Dr. Richardson's method of treating infected puerperæ includes the placing of one or more of these intra-uterine pencils, followed by a free sprinkling of the vagina with iodoform powder. Usually the temperature falls at once, and the patches of diphtheritis, if present, disappear, and no further applications are needed; this, of course, in cases of early detected infection. I am aware that experiments have seemed to prove the feeble germicidal power of iodoform, but here, as in venereal and surgical practice, I think the clinical evidence should outweigh that from the laboratory.

To the statements and position of this paper, some may say: "All is very clear and very well so far as hospital practice is concerned, but such recommendations are entirely uncalled for in private practice in healthy country homes." To these physicians I would quote the words of Dr. T. G. Thomas before the New York Academy of Medicine, in December, 1883: "My observations as a consulting physician convince me that in private practice, even among wealthy patients, who can command every safeguard, there exists a want of system and apathy as to preventive measures which borders very closely upon criminality."

I am very sure that this strong statement now finds support in the views of leading obstetricians of Germany, France, England, and America. The same belief is admirably and forcibly expressed in the excellent book by Kucher, of New York, already referred to. Failure to correctly interpret the symptoms of sepsis has given a false sense of safety. I myself have seen, within a year, two cases of grave puerperal septicæmia with alarming symptoms, whose true nature had not been suspected by the physicians in charge. Who can doubt that the statistics which show such scarcity of this disease in private practice are worthless from the existence of mistaken beliefs, ignorance, or carelessness in diagnosis?

I believe it to be the duty of every accoucheur, not only to carry out the essentials of the antiseptic method most conscientiously in his practice, but also to visit his patient daily during the first six or seven days of the convalescence. This is necessary, not only to make sure, as Lusk puts it, that the patient is not made the victim of the traditions and superstitions of the monthly nurse, but also in order to see that the

directions for antiseptics, previously given, are obeyed, and also to watch the temperature, the pulse, and the progress of uterine involution, that the earliest symptoms of septic infection may be detected.

RECENT PROGRESS IN LEGAL MEDICINE.

BY F. W. DRAFER, M.D.

THE LEGAL RIGHTS AND OBLIGATIONS OF MEDICAL MEN.

Professional Secrecy.—In Great Britain, and in most of the United States, the law recognizes no obligation on the part of medical men to guard as sacred the information which is imparted to them in confidence by their patients. Practitioners of law are the only persons in these States who are not compelled to impart confidential communications, when the courts call for testimony under oath. In Arkansas, California, Indiana, Iowa, Michigan, Minnesota, Missouri, Montana, New York, Ohio, and Wisconsin, physicians are permitted by statute to keep under their own control such facts of a medical nature as have been intrusted to them in the privacy of the sick room, but elsewhere in the United States physicians have no such privileges.¹

In France, and in most continental countries, however, this state of things does not obtain. There the medical man, instead of being punished for contempt of court if he persists in keeping inviolate his patient's confidences, is held accountable for just the opposite course; and the wise aphorism of Hippocrates that whatever information is acquired by the physician in, or even outside, the exercise of his profession should be regarded as an absolute secret, has passed from a tradition or custom into a statute law, with penalties attached to its infraction. To this law (although the statute itself is absolute) there are some exceptions in practice, the medical practitioner being absolved by the judge from the provisions of the statute when he knows of plots against the State, or against the life or welfare of individuals; cases, for example, of poisoning, abuse of children, or criminal abortion. The general principle which governs these exceptions is that the first duty of a physician is to protect his patient, and if the patient is being poisoned, or, as a child, is ill-treated, the medical attendant owes it to his patient to require the help of the law in preventing further damage.

Professor Brouardel has very fully discussed this subject in a work which presents the matter from the point of view of the French practitioner.²

The subject of the obligation of medical men to keep professional secrets has engaged the attention of Italian physicians also,³ and at the last meeting of the Italian Medical Association, Professor Guclù spoke forcibly on the subject, declaring that there are cases in which the physician is bound to preserve absolute secrecy, even if he is summoned to testify in court, and even if he is excused from the obligations of secrecy by the parties interested, for example, in divorce suits, for adultery with syphilitic infection by one or the other of the two persons contesting. There are other

³ *La Semaine Médicale*, Sept. 28, 1887.

eases in which the attending physician ought not to keep silence; because in them the public social welfare is of greater moment than the individual interest; for example, an investigation relative to the health of a betrothed woman, or in epidemics, injuries by violence, cases of poisoning. In these cases the physician indeed should take the initiative in disclosing the facts. In short, according to Guelfi, medical liberty should be enlarged, and the limits of professional secrecy should be restricted.

In discussing the position taken by Guelfi, many members of the association appeared to regard the question as a moral one rather than a legal or professional one. Some, indeed, went so far as to call the obligation of medical secrecy an unjustifiable moral monstrosity, since it often serves to protect vices at the expense of innocent victims. Others demanded for themselves and their fellows complete freedom of action under the guidance of their conscience. The association finally voted in favor of the retention of medical secrecy, and against the practice of giving information concerning corporal lesions.

The Physician's Rights as a Witness.—Mr. Abrams, of the Savannah (Georgia) bar, has reviewed the law as it relates to the rights of the physician as an ordinary and expert witness, and the risks which he runs upon his refusal to testify.⁴ He says:

"A physician, as such, is under no obligation to the public to testify or give his opinion on a subject with which he is peculiarly conversant, because his profession, his skill and knowledge derived from study and experience, are essentially his own property, and no court can deprive him of them without just compensation. In this sense the license to practice medicine, surrounded as it is by numerous safeguards for the public welfare, with laws passed for its proper exercise and punishments prescribed for their violation may be termed a franchise, and his exclusive property.

"The conclusion from numerous adjudicated cases may be stated as follows:

"First: A physician or surgeon cannot be compelled to testify to matters and things, or give his opinion upon matters, derived from his professional skill and knowledge alone. Second: He can be punished for contempt in refusing to testify in a case where he has witnessed an act and is called on to prove it in a court of justice, even though it involves professional opinions; the duty which he owes to the community in furtherance of public justice requires it.

"The urgent need of some settled rules, statutory or other, which shall govern the employment of medical experts, and establish their rights and privileges, is well illustrated in the following contrasted cases:

"1. Dr. F. H. Darby, of Morrow, Ohio, was summoned by the State as an expert in a murder case. He refused to answer the following question unless paid a fee as an expert: 'State whether, in wounds like this, there would be immediate gaping, or would the lips of the wound for a time remain in contact, or nearly so?' The judge declined to grant the fee asked, because he held that there was no law for it, and Dr. Darby, for his refusal to reply, was sent to jail for contempt of court, and he was released only after several days' confinement. He based his refusal on the ground that he was asked to give expert testimony, and as it was not claimed that he had any per-

sonal knowledge of the case the issue was a square one.⁵

"II. In the case of 'State of Michigan *versus* Vanimmans,' the judge said when a physician refused to testify on the ground that his testimony would be expert testimony, 'after many years' study and observation I decide that a physician's knowledge is his stock in trade, his capital, and we have no more right to take it without extra compensation than we have to take provisions from a grocer without pay to feed the jury. The court rules that the witness is not compelled to testify.'⁶

BLOOD-STAINS AND THEIR IDENTIFICATION.

Recognizing the difficulties that attend the examination of blood-stains under the usual conditions—the small amount, and the dried and altered state of the blood—M. Ferry de Bellone treats the suspected stain as follows:⁷

If it is on linen or cotton cloth he cuts it in straight strips and separates the threads with a needle and places them in a small glass tube with a solution of sodium chloride, one part to one thousand. After an interval of a few hours, longer or shorter according to the season and temperature, the liquid takes on a reddish brown color, from the disintegration of the stain. The fluid thus colored can be at once subjected to spectroscopic examination by adjusting the axis of the tube as nearly as possible to the axis of the instrument. The presence of the two characteristic absorption bands near Fraunhofer's band indicates the presence of hemoglobin. This fact having been established—and it is useful in giving information of the presence of blood without touching the liquid—the next step is to search for blood-globules. The fibres of the fabric having been taken out of the tube, after first shaking it so as to detach the cell-elements and cause them to settle to the bottom of the liquid, one or two drops of a concentrated solution of chloral are added. This forms very quickly a red precipitate which seeks the bottom of the tube. When this precipitate is well settled, the clear supernatant liquid is withdrawn with a pipette, and a drop of the red residue is carried to a glass slide. This slide is passed rapidly and repeatedly over the flame of an alcohol lamp. This produces a reddish coagulum, and a clear liquid is separated from the coagulum, which is absorbed and removed by means of blotting paper. Then there remains on the glass slide the coagulum only, in the form of a thin, delicate pellicle. This is stained red with a solution of fuchsin, and when the staining is completed, the pellicle is washed with water by means of a pipette. Then a drop of dilute acetic acid is placed on the specimen, and it is covered with a covering-glass. The preparation is now transparent, and the fuchsin fixes itself in the blood-globules, coloring them a bright red. The microscope now permits one at once to recognize the blood-globules, and to differentiate their special forms and diameters. The blood of ducks and fowls, so treated, has shown the characteristic oval shape of the globules after seven years.

When one has to manipulate blood-stains found on blades of weapons, on a floor, on wood or on stones, the spot is scraped off, and the powder so obtained is placed in a bag of fine cambric. The specimen is

⁴ Cleveland Med. Gazette, July, 1887.

⁷ Gazette des Hôpitaux, Oct. 4, 1887.

⁶ Atlanta Med. and Surg. Jour., April, 1887.

then suspended by a thread in a tube in the solution of sodium chloride.

When the blood is mixed with soil the separation of the globules is more difficult, because of the clay usually found, which settles rapidly in the saline solution. An attempt should in this case be made, with the help of a microscope of low power, to determine the particles which, by their color, resemble blood; and when these have been culled, they may be treated, first, with the saline solution, and then with the chloral. In this case, too, the reaction for crystals of hæmine or chlor-hydrate of hæmatine will be indicated, according to the usual method with glacial acetic acid; and its results will declare whether or not the substance is dried blood. The same reaction, as a control method, is applicable to all such investigations.

Lacour formulates the following conclusions as the result of an extended series of careful studies in the same field of inquiry:⁸

(1) In the majority of cases, when total decomposition has not occurred in the specimen, one can recognize the presence of blood in suspected stains, even after the lapse of several years, by using the methods of micro-chemistry and spectroscopy.

(2) If skill and care are employed, one can distinguish human blood from that of bullocks, sheep, and oviparous animals. The search becomes much more delicate when one has to do with the blood of the dog or the rabbit, and a distinction between human blood and that of the guinea-pig is altogether impossible. The globules of other domestic animals resemble more or less those of the human subject in their diameter, but can all be differentiated.

(3) One can certify that he finds in the specimen of blood examined blood-globules which, in all respects, are like those of man or the guinea-pig, when the average of his measurements gives a number above $\frac{1}{17}$ of a millimeter; but if there be much variation from this average, it shows that they may have come from a dog or a rabbit.

RAPE.

The Gonococcus and its Recognition. The medical jurist often has to determine the true nature of a urethral or a vulvo-vaginal discharge, and to be in a position to state whether the pus is or is not gonorrhœal. Lober, of Lille, has undertaken a series of observations whose results are an essential aid to diagnosis.⁹ All fluid discharges from the parts mentioned contain micrococci, and pus, especially, displays several varieties of them. The one character which, according to Lober, distinguishes the specific gonococcus is the property which it possesses of decolorization when the staining method of Gram is employed. Appreciating the difficulty of differentiating this microbe in the midst of a great number of others by the simple process of staining the specimen submitted for examination, Lober resorted to cultivation as a means of diagnosis. He tried cultures in bouillon and agar-agar, peptonized and sweetened. The latter gave good results. After having liquefied the agar-agar previously sterilized in glass tubes, and having mixed with it the fluid to be examined, he spread the preparation on a glass plate, and placed it under a sterilized bell glass. The cultures were kept at a

temperature of from 12° to 20° C. On the third day there appeared, as a uniform result, on the surface of the cultures of gonorrhœal pus, small white points, which, the next day, became spots of the size of a pin's head, and later, spread more and more. If one colored these colonies with methyl violet, they were found to consist of various forms of micrococci and diplococci. Treated according to the method of Gram and with alcohol, all the elements became decolorized. The results, as described, were uniform when gonorrhœal pus was used for the cultivations. Often, alongside these white colonies, there appeared yellow groups; these were colonies of staphylococci which retained their staining.

Lober was successful in colonizing and recognizing gonococci by the above method, derived from pus-stains found on the shirt of a man charged with rape, and on the chemise of his victim. Microscopic examination and staining of a macerated portion of the same spots confirmed the culture results, by detecting the presence of the gonococcus in the pus-cells. When non-specific pus was used as the material for the culture process, the micrococci, streptococci, and staphylococci found in the colonies were not decolorized by the method of Gram.

CAN A WOMAN BE RAVISHED WITHOUT HER KNOWLEDGE DURING HYPNOTIC SLEEP.

Brouardel believes this to be possible only under certain very favoring conditions.¹⁰ If a man who is agreeable to the somnambulist offers suggestions to her which are acceptable and of an indifferent character and not offensive, she submits herself to them; but if the suggestions are revolting to her personal affections or her natural instincts she opposes to them a resistance which is almost insuperable. One may easily lead the hypnotized subject, for example, to sign a receipt for money; but if she has preserved her normal chaste instincts, anything contrary to those instincts will be sought in vain. But, on the contrary, if the sentiments and the acts offered by the magnetizer to his subject correspond with her own, she obeys readily his suggestions. In the great majority of cases, however, a woman does not recall in her waking state what happened to her in the state of somnambulism and *vice versa*, yet the same feelings affect her in both states.

SEXUAL INCAPACITY.

Hermaphroditism.—According to Brouardel,¹¹ a true and genuine hermaphrodite is a myth. Hermaphroditism, so far as it relates to the internal sexual organs, has been found; but its coexistence with the external attributes of both sexes is impossible. During the first six weeks of intra-uterine life, the fœtus is both male and female; according to the predominance of development of the gland of Müller or the Wolffian body it becomes male or female. It can readily be understood that if the development is parallel, it might result in the coincident formation of an ovary and a testicle which ordinarily remain in a rudimentary condition. It is quite different with the external organs. During the first two or three months, determination of the sex of the fœtus is extremely difficult; one observes something like the rudiments of a penis which is destined to become either a clitoris or a

⁸ Archives de Med. et Pharmacie Milit., October and November, 1887.

⁹ La Semaine Médicale, March 9, 1887.

¹⁰ Gazette des Hôpitaux, November 8, 1887.

¹¹ Gazette des Hôpitaux, January 1, 1887.

penis. The scrotum is cleft in the median line; the closure or non-closure of this cleft determines whether a true scrotum or a vulva shall be the result. But it is easy to understand that we cannot have at the same time in the same person closure and separation of the parts, a scrotum and labia majora. Complete hermaphroditism, therefore, cannot exist; we may find simply malformations capable of raising doubt as to the true sex.

With regard to hermaphroditism of the internal organs, Brouardel recognizes four chief varieties: we may find (1) two ovaries and two testicles, (2) two ovaries and one testicle, (3) one ovary and two testicles, and (4) one ovary and one testicle. Examples of either of these varieties are extremely rare. To these should be added a fifth and still rarer abnormality, in which the individual (a male) has two testicles and something like a uterus.

The cases which have a more immediate practical interest in their medico-legal relations are those of pseudo-hermaphroditism, which consists generally in an arrest of development of sexual organs in the male and in an excess of development in those of the female; of the former, a typical example is hypospadias. The subjects of this deformity are usually cryptorchids. In the female, spurious hermaphroditism is found illustrated in an exaggerated development of the clitoris; to this is joined sometimes an obliteration of the vulva. In hypospadias, the rudimentary penis shows at its base a groove, a kind of cutaneous-mucous frangium beneath it; this the author has never found upon the clitoris, and it is in his opinion an essential characteristic of the male sex. Then, on the other hand, the cleft scrotum of the hypospadias, showing in its two halves a resemblance to the labia majora has nothing analogous to the labia minora; there is no case of a hypospadias with nymphæ or a hymen.

Clinical Memorandum.

SINGULAR SUCCESSION OF SYMPTOMS IN A CASE OF MALIGNANT DISEASE.

BY GEORGE A. OVIATT, M.D., OF SOUTH SUBBURY, MASS.

MAY 10, 1880, I was called to see Mrs. M. G., who had been suffering for some weeks from loss of sleep. She was fifty years of age, the mother of one child, and had had one miscarriage, fifteen years previous to my visit. She was of unusually dark complexion, of medium height, rather thin, and had just passed the change of life. She had never been ill, and had been able to perform her accustomed duties without any assistance, save at the time of her confinement.

I found her suffering not only from insomnia, but melancholia. She was much disturbed lest the family should come to want, although in very comfortable circumstances. She had been taking bromide of potassium with some preparation of valerian, but had not been much benefited thereby. I ordered large doses of the bromide combined with chloral, after taking which she was able to get more sleep, but the depression of mind was in no way relieved.

At the end of a week an eruption of a bright red color appeared on her lower extremities and trunk, showing a decided tendency to spread. The second day after it was discovered it had assumed a darker

shade, and covered almost the entire body. At first, I had supposed it to be caused by the large doses of bromide of potassium administered, but now thought it must be cutaneous erysipelas. The pulse, on the morning of the second day, was 120 a minute, the temperature 104°. The heart-sounds were weak, and that organ seemed taxed to its utmost.

The third day, in view of the gravity of the symptoms, I requested a consultation, and Dr. Z. B. Adams was called in. He confirmed my diagnosis of erysipelas, and feared that there would be a failure of the heart's action, as almost all the cuticle was involved. It was decided that twenty drops of tincture of chloride of iron and a desert-spoonful of whiskey should be given in alternation every two hours. The topical application used was a solution of acetate of lead, applied, where it could be, with any convenience.

At the end of six days the erysipelas departed, followed by a very marked desquamation, large patches of old skin coming off in many places, leaving a new and very sensitive cuticle in its place. During all this time the melancholia had been absent, and the patient had been able to sleep well, except when kept awake by the itching of the cuticle.

As bodily health returned the mind was again affected, and as badly as before. At her husband's request, I saw Dr. C. F. Folsom, and by him was encouraged to think that after the change of life was fully established the melancholia would cease. He advised a change of scene for six months, and lively company. About this time, a tumor was detected by the nurse in the left breast, with retraction of the nipple. This the patient was very anxious should not be brought to my notice.

In the autumn, the tumor gave her so much uneasiness that she consented to have a careful examination made, when it was pronounced a cancer. She went to the Massachusetts General Hospital, where the tumor was removed. After this, for a year she was in the best of spirits, and considered herself quite well. At the end of a year she was again compelled to go to the hospital for a second operation. Six months after the second operation, she placed herself in the hands of a quack to have the cancer drawn, as it had again appeared, and was very painful. This last treatment was pronounced to have been entirely successful. Three months after I was called in, as the left arm was very much swollen; there was a great deal of pain, and from a small cavity in the axilla a thin, watery pus of a characteristic odor was exuding. The melancholia was very marked. The dread which the patient had lest she should be obliged to go to the almshouse, was much greater than her fear of present suffering. Morphine was injected subcutaneously every night; otherwise she had no sleep.

Three months before her death, a rodent ulcer of cancerous nature appeared in the lumbar region, which rapidly increased in size from that of a quarter of a dollar to the circumference of an ordinary teacup. A very small one also appeared just above the nape of the neck. They both had irregular, purplish edges, and the pus had a very offensive odor. In the lumbar region, the vertebrae were almost exposed.

She was able to sit up until within a few days of her death, and went to bed only at night. She was very unwilling to have any one take care of her, save her husband, and only consented to have a nurse when her husband's illness made it absolutely necessary.

The remarkable features of the case were these: The rapid development in such quick succession of, first, insanity; second, severe attack of erysipelas, involving all the cuticle; third, the appearance of three cancers of the breast within two years and a half, accompanied, at last, with rodent ulcers in two other regions; fourth, the fact that the mind was the least affected at the time when the erysipelas was in progress, and the breast most painful, except at last, when the melancholia was constantly present.

Reports of Societies.

ESSEX NORTH DISTRICT MEDICAL SOCIETY.

The regular quarterly meeting was held in Haverhill, at the Eagle House, January 4, 1888, and was called to order by the President, E. P. HURD, at 11.45 A. M.

The Secretary announced the death of Dr. David Dana at his residence in Lawrence, December 10, 1887, at the age of sixty-two years, and of Dr. James R. Nichols, of Haverhill.

Dr. CROWELL moved that Committee be appointed by the chair to draw up fitting resolutions.

On the death of Dr. Dana, the chair appointed the following Committee: Dr. Woodbury, of Methuen, Drs. Chamberlain and Carleton, of Lawrence. On the death of Dr. Nichols: Drs. Crowell, Clarke, and Lovejoy, of Haverhill.

The President then introduced Dr. PHILIP COOMBS KNAPP, of Boston, who read a paper on

SOME EARLY SYMPTOMS OF TABES DORSALIS.

THE PRESIDENT asked the essayist whether silver nitrate, which was once spoken of with some favor, is now considered a good remedy in tabes.

Dr. KNAPP answered that he had used it, but was doubtful of its efficacy. He had seen much more decided benefit from potassium iodide, sixty to ninety grains, three times a day. He thinks that it is best given in Vichy, or largely diluted in plain water.

Dr. H. F. ADAMS, of Newburyport, read a paper on

ANTISEPTIC MIDWIFERY.¹

He exhibited several books to which reference was made in the paper, and showed several forms of the occlusion pad.

Dr. WILLIAM COGSWELL said that he had never seen the necessity of antiseptic precautions in his private obstetric practice. In an experience of over forty years he had never had any puerperal peritonitis, and he had never taken any precautions beyond washing his hands with whatever soap was handed him.

Dr. LOVEJOY agreed with Dr. Cogswell. He had had no peritonitis. He had occasionally seen swelled legs, but that came from scattering of the milk. In nearly all cases of swelled legs he had found the milk suppressed, and a lump in one breast.

Dr. STABLER said that he had not been so fortunate as Dr. Cogswell. He had, from reading, become convinced of the need of antiseptic precautions, and had so expressed himself before the Lawrence Medical Club, but the proposal to introduce it into private practice had met with such unanimous disapproval

from the older members, that he had become somewhat careless in his application of it. Following this, he had had in private practice, last summer, a most pronounced case of puerperal fever. An intelligent lady in good circumstances, who was confined in a house containing an untrapped drain, was taken with a chill the next day after delivery. Her temperature rose steadily for a week, till it reached 106°, and she only recovered after four weeks of fever of typhoid type.

Dr. R. C. HUSE said he had in times past lost several cases from puerperal septicæmia. In the case of his own wife, when he found her with a chill and rising temperature, he had given a vaginal injection of a solution of chloral hydrate, the strength of which he regulated by tasting it before making the injection. The effect was very happy, and he had repeated the practice in several subsequent cases with equally good results. He has also used Lugol's solution of iodine, one drachm to the pint of hot water, with the effect of promptly deodorizing offensive lochia. He now always uses antiseptics, and since adopting the practice he has had no septicæmia.

Dr. CLARKE said he thought we had not the courage of our convictions. *Antiseptic midwifery* implied the absolute exclusion of germs from the parturient canal. The half-way use of germicides is not antiseptic midwifery. For his own part, although well acquainted with septicæmia, having seen it in all its horrors at the Boston Lying-in Hospital, he has had no cases of the disease in private practice. Antiseptic midwifery presents so many difficulties for the private practitioner who has been trained in the methods of earlier years, that he (Dr. Clarke) does not expect to attempt it until he shall have had a case of septicæmia.

Dr. HUSE, in reply to Dr. Clarke's implied assertion that he used half-way measures, would like to state what his measures are: On first seeing the patient, and before any vaginal examination is made, he gives her an enema, washes out the vagina with 1-3000 solution corrosive sublimate, and has the external genitals bathed with 1-1000 solution. He then washes his hands with soap and with 1-1000 solution, and introduces the finger without ointment, and *never* allows himself or any one else to touch the patient's genitals without first having washed the hands in the solution. After the delivery of the secundines, he washes the patient with the antiseptic and calls for two towels. One of these he dips into the 1-1000 solution, and after wringing it out with his hands, he folds it into a square pad and places it over the vulva. The second towel he likewise wrings out of the antiseptic, and folding it once likewise, passes it between the legs, and pins it to the binder at front and back. When instruments are used, he immerses them for an instant in boiling water.

Dr. STABLER called attention to a point recently stated by Weir, of New York, that dry preparations of mercuric chloride are unreliable, because the bi-chloride is so quickly changed into calomel. Pathogenic microbes have been found in dry pads that were previously impregnated with sublimate. With regard to the ointment used for the finger and instruments, he had used both carbolic acid and eucalyptol. Both have strong odors, and the carbolic anaesthetizes the examining finger. He prefers a five per cent. ointment of resorcin.

¹ See page 216 of the Journal.

PROF. WILLIAM L. RICHARDSON, in closing the discussion, said he had been fourteen years at the head of the Boston Lying-in-Hospital, where septicæmia had been so prevalent that they had repeatedly been compelled to close the Hospital. Since the introduction and adoption of the antiseptic method in 1885, they have had over nine hundred confinements, without a death from septicæmia. With regard to diagnosis, he thinks peritonitis a comparatively rare complication of septicæmia, but regards a temperature of more than 100° F. as evidence of it. Milk fever, swelled legs, mammary abscess, sore nipples, pneumonia, are all evidences of it. Under the antiseptic method, women pass through the puerperal period without any rise of temperature whatever, and torn perineums unite by first intention without the slightest difficulty.

He considers the physician responsible if a death occur from any of the above enumerated causes. In his opinion, the question is bound to assume a medico-legal aspect, and it will go hard with a physician who loses a patient from any such cause, unless he can succeed in shifting the responsibility on to the nurse. With regard to technique, it makes no difference whether pads or towels are used, or whether the pads were used wet or dry. Garrigues uses them wet, but in Boston they are used dry, because the wet pad, if long continued, may cause eczema, and possibly, mercurial poisoning. He has abandoned the post-partum douche, except in cases where it is positively indicated.

There is little danger of absorption from the endometrium, but much more danger that the mercurial will be absorbed in the folds and small rents so constantly present in the vagina. Digital examinations may be practised *ad libitum* previous to delivery, provided the examining finger be washed in the mercurial before introduction.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.¹

SECOND DAY.—AFTERNOON SESSION.

DR. WALTER SCUTER read a paper on

THE PRESERVATION OF DEAD BODIES,

in which he showed there had not been the advances in this line over old time methods, as there had been in other departments of medical science. He briefly described methods ordinarily employed by undertakers, and showed that the preservative agents were commonly of a kind which would make it impossible to detect the crime of poisoning by examination of the fluids of the body after the embalming process. Most of the agents contained metallic poisons, especially arsenic. He moved that the committee on legislation be given power to investigate the subject with a view, if necessary, to urge legislation limiting the embalming fluids to be used by undertakers. The motion was adopted.

DISCUSSION ON INTESTINAL OBSTRUCTION.

DR. LEWIS A. STIMSON, of New York, opened the discussion with a paper on

THE PATHOLOGY AND SYMPTOMS OF INTESTINAL OBSTRUCTION.

The author described the various forms of intestinal obstruction, including that due to constricting adhe-

sive bands, internal herniotomy, various forms of volvulus, twisting of the gut upon itself, intussusception, obstruction by accumulation of faeces, by pressure of tumors, foreign bodies in the gut, etc. Among these was to be included that common group of intestinal cases of intestinal obstruction called functional obstruction, depending on some local inflammatory process. Clinically the cases were divided into acute and chronic, and symptomatically into those which came on without previous warning, and those which were preceded by pain, etc. The great difficulty lay in diagnosing the chronic cases. Among symptoms common to all cases were local or general peritonitis, originating at the point of occlusion; marked distension of the upper segment of the bowel, and marked contraction or emptiness of the lower one. Dr. Stimson took up the individual symptoms in the different cases. The tendency of all cases of acute obstruction was to become constant. A study of the cases of acute obstruction showed that all might be grouped into two classes; the first, and much larger class, being those in which relief could not be obtained except by active operative interference; second those in which there was a possibility of relief by other means. In intussusception and stricture of the large intestine there were two symptoms not found usually in others, namely, tenesmus and bloody and mucus passages. The author then considered some of the points of differential diagnosis between acute obstruction and conditions giving rise to like symptoms, symptoms of peritonitis, etc., statistics relating to these particulars were too meagre.

On motion the president was empowered to appoint a committee which should ask for and receive communications from physicians throughout the State, giving their experience with intestinal obstruction.

The discussion was continued by DR. WILLIAM C. WEY, of Elmira, with remarks on

HOW LONG SHOULD CASES BE TREATED MEDICALLY?

He said that if the peritoneal cavity could be entered with the immunity from danger which some claimed at the present time, these cases should not be treated medically at all. There were certain cases in which he believed it to be impossible to make a diagnosis. We had certain rules which seemed to be pretty well established with regard to locating troubles in the small or large intestine, but when the physician got to the bedside he found often that such knowledge went for naught. Except in large cities where the surgeon was ever convenient and ready, cases of intestinal obstruction were usually allowed to go on under medical treatment until death closed the scene. But he had seen cases with all the marked symptoms of obstruction recover under medical treatment. He related one case in which relief had been obtained by aspiration. Medical treatment should be continued until such time as serious symptoms gave positive indications for surgical interference, and when that time arrived we should not hesitate about operating. The opportunity to resort to surgical interference in the country seldom occurred.

DR. ALBERT VANDERVEER, of Albany, discussed the question

WHEN SHOULD OPERATIVE MEASURES BE RESORTED TO?

He said: It must be evident to us all that the gen-

¹ Concluded from page 203.

eral practitioner can no longer look upon an autopsy revealing the cause of intestinal obstruction and quiet his own thoughts, as well as the inquiries of friends, by saying: "Well, nothing more could have been done than the medical treatment adopted," had he known as we do now, the true condition of affairs. It becomes the duty of every man, at the present time in general practice, to acquaint himself with all that pertains to the causes and symptoms of intestinal obstruction.

When an early diagnosis has been reached, when a careful and well-conducted consultation has been held, and a judicious and cautious but thorough medical treatment has been tried, we should then consider intelligibly and resolutely the chances of an operation. These cases should not be left until symptoms of shock have become too pronounced, or until a condition of actual collapse is present. But we are often obliged to wait until the border-land is crossed, and we are well on, or it may be into the dangerous ground of heart-failure and allied conditions, before the patient or friends will grant consent to surgical interference. We need now to have successful cases to teach the public the possibilities of what surgery can do in these heretofore fatal cases.

DR. A. G. GERSTER, of New York, dwelt upon the necessity of making a careful study and examination in all cases of intestinal colic, since so often obstruction began with the same symptoms as a colic, and if the case went on to the point of great distension of the abdomen from tympanites, it would be almost impossible to feel a tumor or the cause of the obstruction.

DR. WEIR was disposed at present to think that when there were ordinary symptoms of obstruction, as pain and persistent vomiting, lasting twenty-four or forty-eight hours, the case should be passed over to the surgeon.

DR. W. GILL WYLIE spoke of certain cases in which there was partial intestinal obstruction, in which there was likelihood of a fatal termination more quickly than in complete obstruction. They were those in which the symptoms began with chill, sweating, together with those of obstruction. They pointed to a tumor containing pus. He had recently had two such cases, in one of which he operated without allowing a medical consultant to be called, as he knew it would lead to delay, and probably, thereby, to death. He found an abscess, which he removed, and the patient recovered.

After some further informal discussion, DR. ROSWELL PARK read a paper on

WHEN SHOULD ENTEROSTOMY BE CHOSEN?

When a case of acute intestinal obstruction was seen very early, exploratory laparotomy might be justified, but when seen very late, enterotomy was probably the only justifiable operation. Laparotomy was especially indicated when obstruction was early recognized, or its presence was reasonably certain; when caused by a tumor, by a neoplasm which could be removed, and when the condition of the peritoneal cavity demanded washing out or drainage. Enterostomy would be indicated when the surgeon could form no idea of an obstruction; when malignant nature of the obstruction precluded any possibility of permanent benefit from its removal; when the patient's powers were too far undermined, etc. Laparotomy was the

more practical surgical measure, but it was, at the same time, more dangerous than enterotomy or enterostomy.

DR. ROBERT F. WEIR, of New York, discussed

HOW SHOULD THE OPERATION BE CONDUCTED?

While he had used ether, he now believed chloroform would be the better anesthetic, and should be administered by the Esmarch inhaler, which permitted of the admixture of a large amount of air. Sometimes a view of the abdominal cavity could be obtained by retaining the intestines in place by sponges, but the distended condition of the intestines seldom permitted this. After all, laparotomy for intestinal obstruction resolved itself into the treatment of the distended gut. How were we to manage that condition? Rapidity of operation was the salvation of these patients. He would make an opening allowing of free exposure of the abdominal contents. The author described the steps to be taken after opening the abdomen in the different forms of obstruction. When the gut was obstructed by a gall-stone, one operator had broken up the gall stone by a needle introduced through the gut, and another had urged it along down the small intestine until it reached the large intestine, where it was allowed to remain. In invagination it might be necessary to remove a portion of the gut, and quite a considerable amount had been excised, the patient still recovering good health. If antiseptics were employed in the peritoneal cavity, salicylic acid should be preferred to carbolic acid or corrosive sublimate. It was potent and safe. After the operation, little nourishment should be given by the mouth. Opium should be avoided. If there were threatening peritonitis, catharsis, as recommended by Mr. Tait, should be employed. Dr. Weir insisted upon the necessity of operating early.

RESULTS OBTAINED BY OPERATIVE INTERFERENCE.

DR. B. FARQUHAR CURTIS, of New York, had collected a table of 336 cases of laparotomy for acute intestinal obstruction since the statistics given by Schramm. The mortality had been 68 per cent. Death was due in over one-half of the cases to the condition of the patient at the time of the operation. The mortality was greatest in the longest operations. Enterostomy had given a mortality of 67 per cent. It would have to give much better results before it could compete with laparotomy, for it was not curative.

DR. A. JACOBI said it had often been advised to puncture the much distended intestine, but he called attention to the danger of this procedure, leaving an aperture which would fail to close, and permit of extravasation of feces and the development of peritonitis. He had seen such a case.

DR. BACON, of Hartford, cited three cases recently seen by him, in two of which he relieved acute intestinal obstruction by injections of water through a long tube, the patient's head being low. It was somewhat doubtful whether laparotomy would have resulted as favorably. In the third case an operation was refused, and the patient died.

DR. R. B. BONTECOU, of Troy, presented a young man on whom he had performed laparotomy for acute intestinal obstruction successfully, and cited another recent and successful case. In one case, the duration of the entire operation was eighteen minutes.

SECOND DAY. — EVENING SESSION.²
THE PRESIDENT'S ADDRESS.

DR. A. L. LOOMIS, in the introductory remarks to his address, traced the methods of medical study in different ages, the advantages and disadvantages attending investigations by physicians at different periods. The simple inscription on the tombstone of one of the fathers of New England medicine characterized the present medical era: "The Disciple of no Man."

Dr. Loomis discussed four problems of interest at the present time:

- (1) The relation of microbes to disease processes.
- (2) The prevention or modification of disease by inoculation.
- (3) What is the cause of abnormal rise of temperature in disease?
- (4) What is the value of antipyretics?

In connection with the first problem, he discussed the question whether microbes could originate *de novo*, and whether there was mutability of bacteria, and said he thought the affirmative of these questions had not been proven. The question, do microbes act as the sole cause of disease? was more difficult to answer. The President named some affections in which it had been shown that they were the sole cause — erysipelas, remittent and splenic fevers. To his mind, it had not yet been positively proven that the bacillus tuberculosis was the sole cause of phthisis.

Regarding the second problem, he said the fact that persons who had had certain infectious diseases were not afterward liable to contract those diseases, favored the view that diseases might be prevented or much mollified by inoculation with an attenuated virus of infectious diseases. Experience had shown that the diseases which can be prevented by inoculation are vaccina, variola, splenic fever, and, if we could accept the report of the English Commission as conclusive, hydrophobia.

Regarding the third problem, its answer involved an answer to the question, What is fever? Something which the profession did not yet understand. It seemed almost self-evident that a prominent factor of heat production existed in metabolism. There seemed to be imperative necessity for some regulative mechanism, but he could not understand why there should be a nervous mechanism which should control heat-production without there being corresponding changes either general or local. He could conceive of no reasonable evidence against the view that physical processes must be governed by the same laws and be productive of the same results in every instance and under all conditions. It had been pretty conclusively shown that there is an inhibitory center upon heat-production, but its exact location had not been demonstrated.

Regarding the fourth problem, the effects of antipyretics in the treatment of disease, Dr. Loomis said that when antipyretics were used to cause reduction of high temperature, and the temperature remained reduced only for a short time, he was confident that such reduction took place at the expense of the vital forces of the patient. He thought that no one whose experience was at all extensive in the use of antipyretics in infectious diseases, would for a moment claim that they have any power in shortening their duration

or greatly modifying their severity. There were two kinds of antipyretics, those administered internally, and the application of cold to the surface. The mode of action of the two was evidently different. Their use was based only on the fact that they removed one of the phenomena of fever. If this could be accomplished without serious loss of vitality or at the expense of the reserve forces of the patient, we were justified in their use; but we should not imagine that by reducing the temperature we control the fever. Dr. Loomis paid a high tribute to the tendency toward experimental study, but he said it should not be elevated above the clinical in medicine.

THIRD DAY. — MORNING SESSION.

A number of papers were read by title, and referred to the committee for publication in the "Transactions."

REMARKS ON THE "CHIAN TURPENTINE TREATMENT OF CANCER."

DR. DANIEL LEWIS described the drug, the precautions in its selection as laid down by Clay, of England, and the results obtained from its use by that gentleman. Dr. Lewis had not had sufficient experience with the drug to draw any conclusions as to its efficacy.

DR. JOHN O. ROE, of Rochester, read a paper on

THE FREQUENT DEPENDENCE OF PERSISTENT AND SO-CALLED CONGESTIVE HEADACHES UPON ABNORMAL CONDITIONS OF THE NASAL PASSAGES,

which was discussed by DR. C. R. AGNEW, who agreed with the author regarding the dependence of general or local diseases, remote from the primary seat of irritation, but impressed caution among specialists against apparent attempts to unduly impress the importance of their own department in medicine.

The following officers were elected: For President, DR. S. B. WARD, of Albany; for Vice-president, DR. A. WALTER SUITER, of Herkimer; for Treasurer, DR. C. H. PORTER, of Albany; for Secretary, DR. WILLIAM MANLIUS SMITH, of Syracuse; Committee of Arrangements, DRS. E. L. PARTRIDGE, F. C. CURTIS, C. S. MERRILL; Delegates to the Massachusetts Medical Society, DRS. A. JACOBI, J. O. ROE, B. A. SHERMAN.

The Special Committee, appointed by the President to report at the present meeting on the question of substitution of National for State quarantine, reported that they could not give satisfactory answer to the propositions involved, within the limited time of this session. The committee was continued and given full power to act with committees appointed by other State Medical Societies.

DR. C. R. AGNEW, of the Special Committee, with relation to the insane, reported: (1) That until comparatively recent times, the insane were considered and treated as criminals, and confined in dungeons or prisons; (2) Their subsequent retention in poorhouses was essentially a return to the old system; (3) The treatment of the insane has improved with the progress of civilization; (4) Therefore special hospitals were supplied for them, and their welfare was entrusted to scientific and humane people; (5) A return to anything like the old system of treating the insane in poorhouses, or relegating them to the mercies of county officials would be a grave mistake. The Medical Society of the State of New York therefore expresses its objection to any plan or law which in any

² Held in the Senate Chamber of the Capitol.

way looks to a return of the insane to county poor-houses, as being unscientific and inhumane.

After some discussion the report was adopted.

The thanks of the Society were extended the President for the marked ability and satisfactory manner in which he had presided over the meetings.

Adjourned.

THE NEW YORK ACADEMY OF MEDICINE.

STATED MEETING, February 2, 1888.

DR. ROBERT W. TAYLOR read a paper on

XERODERMA PIGMENTOSUM AND ITS RELATION TO MALIGNANT NEW GROWTHS OF THE SKIN.

It was in 1870, he said, that Hebra and Kaposi published in their book the first account based on the observation of four cases of this skin disease, which was peculiar to childhood, multiform in its clinical characteristics, and indelible in its disfigurements. It was especially destructive to the eyes, nose and mouth, and by its subsequent new growths was liable to lead to death. In 1877, Dr. Taylor read before the American Dermatological Association, at its first annual meeting, held at Niagara Falls, a paper giving the histories of seven cases of this affection, all of which had been under observation for a number of years. At the same meeting Dr. C. Heitzmann, of New York, also reported a case. At the next annual meeting of the Dermatological Association, which was held in 1878, at Saratoga Springs, Dr. Taylor read a second paper on this subject and the paper which he now presented to the Academy of Medicine, he said, embodied the results of his observations and studies for fifteen years.

In 1878, Duhring also reported a case, and 1882 Kaposi published a valuable paper on the disease. In 1883, Neiser reported two cases, and published with them an account of six cases observed by Rüder. In the same year Vidal's paper appeared. In 1884, Pick published a paper, and the same year Crocker also published one containing the histories of three cases, the only ones hitherto observed in England. In 1885, Kaposi reported his ninth case, and the same year Dr. J. C. White, of Boston, also reported one. Altogether forty cases had been observed up to the present time, but at least one of these had to be rejected, as not being in reality an instance of the disease in question. There was more or less doubts about the diagnosis of some of the others, on account of the lack of data concerning the early stage, but, notwithstanding the absence of this desirable information, he was willing to accept them.

Dr. Taylor then proceeded to give in detail the history of some of his cases. Three of them occurred in one family and two of them in another family, closely related to the other. All his cases were in females, with one exception. In one of them in which there were numerous vascular tubercular elevations, there was a supra-orbital tumor of considerable size, which was operated upon by Drs. Gruening and Gerster, and later it was found necessary to enucleate the eye-ball. The one boy who was the subject of the disease, when seven years old was attacked with mumps, and, resulting from this there was an abscess, which had to be opened. The wound thus made never healed. Extensive ulceration followed, and this finally involved the coats of an artery, in

consequence of which uncontrollable hæmorrhage occurred, from which the patient died. Another of the children died of marasmus, and still another was accidentally drowned.

In these seven cases, Dr. Taylor said, all the clinical features of the disease were portrayed. The affection consisted essentially of telangiectases, pigmentations and atrophic changes, to which were supra added certain polymorphous new growths which primarily were benign, but which were liable to degenerate into malignant tumors. In six of the cases the disease commenced when the children were about seven months old, and in the seventh at the age of fourteen months. The weight of evidence placed this disease as one of very early childhood, and he laid great stress upon the prodromal erythema, the usual seat of which was on the face under the eyes, and which was liable to be mistaken for sun-burn. It occurred in infants in good health, and without apparent cause. This prodromal hyperemia lasted from one to three months, and as it gradually disappeared, the pigmentations began to make their appearance. They affected the face and the exposed parts of the neck and extremities; often extending as low as the third rib on the chest, and up to the elbows on the arms. They varied in size from a pin-head to a lentil and were not much elevated above the surface. Scattered among them were red or telangiectatic spots, in which congeries of capillary bloodvessels could be distinguished with a strong glass. Upon the hands there was much less of the prodromal erythema than upon the face. In the meanwhile there were no marked local subjective symptoms, heat, burning and itching being absent, and the general health remained good. The lesions were always characterized by alternating exacerbations and periods of inactivity, so that the course of the disease was more or less erratic.

The period of the pigment-spots and the telangiectases belonged principally to early childhood, and these two orders of lesions were peculiar to the stage of hypertrophy. The atrophic changes usually made their appearance at the end of the first year. The atrophy was not, as a rule, symmetrical, and varied greatly in extent and intensity in different subjects; while it was not commonly as well-marked on the extremities as on the face. This atrophy of the skin, developed in accordance with the atrophy of the bloodvessels of the telangiectatic spots. It was especially apt to affect the eyes, nose and mouth; causing ectropion, with its attendant evils, and deformity of the nasal and oral cavities. Very often hypertrophic changes were taking place at the same time as the atrophic. The course of the primary disease could then be briefly described as follows: First, there is, after a general hyperamic stage, dilatation of the capillaries; then these increase in size by new growth of their elements. This gives rise to the red spots, which constitute the first stage of the disease. After remaining a variable period, these minute capillary new growths undergo atrophy, leaving on their site brown spots. This constitutes the second stage, while the third is occupied in the continual new growth of vessels upon the site of those already obliterated in the atrophy of the skin itself.

The pigmented spots, or freckles, were not necessarily permanent, but in certain localities, particularly where atrophy existed, they came and went, fading,

and being replaced by other similar spots. They varied in color from a light brown to black, and invariably appeared in the exact positions previously occupied by the red ones, constituting a new formation of the superficial capillaries. If these changes were carefully studied in any part, it was observed that a vessel first underwent enlargement and became prominent, forming a red spot, and then it disappeared by atrophy, the brown spot, partaking of the conformation of the vessel spot, being left.

The face presented a mottled appearance, and, in addition to the freckles and the red spots, there were found white spots varying from a quarter-of-an-inch to an inch in diameter. There was a want of elasticity of the skin, which was like parchment, or seemed as if it had been coated with inflexible collodion. The appearance presented not infrequently resembled the cicatrix of an extensive but superficial burn. There was an almost total absence of the normal secretions and there was apt to be a peculiar immobility of expression upon the countenance. In some cases, however, the atrophy was much less marked than in others, and it was always less pronounced upon the hands than upon the face. The atrophic condition, in general, was not unlike that met with in senile atrophy of the skin.

While the atrophic changes were to be dreaded on account of their liability to result in hideous deformity, the keratotic or warty patches which eventually grew from some of the pigment-spots, were liable to degenerate into malignant growths. There were two principal forms of new-growths: (1) The keratotic, and (2) the larger, or elastic, which was in reality simply an exaggerated form of the first. Malignant new-growths were recorded in sixteen out of thirty cases, and non-malignant in six cases. In nine cases in which there were as yet no new-growths, six of the patients were under the age of twelve. Out of Dr. Taylor's own seven cases, epitheliomata was found in three. It was to be borne in mind that in any of the six cases with benign new-growths, these growths might at any time become malignant. The statistics served to show that in this disease the greatest malignancy was exhibited under the age of ten years, nearly as great between the ages of ten and twenty, and after that a diminished tendency to malignity. It was certainly a singular fact that epithelioma should develop in such young subjects. There was no evidence of metastasis in any of the cases.

Having remarked that it was impossible to give an exact description of all the tumors met with, Dr. Taylor proceeded to present the views of Kaposi, Neiser, and Pick in regard to the pathology of the disease. The horny layer of the skin was thickened and desquamating, the stratum lucidum and stratum granulosum disappeared, the Malpighian layer was thinned, and its deeper cells were strongly pigmented. The derma was atrophied, the papillae were quite apparent, and certain masses of pigment were seen; numerous embryonic cells were met with, and a quantity of elastic fibres, which appeared to have replaced the connective tissue to some extent. The vessels, the smooth muscular fibres, the sudoriferous glands, and the pilo-sebaceous follicles were diminished in number, and tended to disappear. The fungous tumors usually presented the histological characters of epithelioma, and the most common disposition was that of a lobulated epithelioma, with the fibrous stroma

infiltrated with embryonic cells. In some instances the new growth was found to be of the nature of angio-myxoma.

Intelligent medication, extending over several years, had proved quite ineffectual, and no case of the disease had ever been cured. In the treatment, measures should be taken to keep the skin at rest and free from all sources of irritation. All pigmentation warts should be removed as soon as possible with the spoon. All large tumors should also be extirpated, and the subjacent tissues thoroughly scraped, if necessary, to the bone or periosteum.

In answer to a question from the President, Dr. A. Jacobi, in regard to the absence of connective tissue, Dr. Taylor said that in this disease the papillae were principally involved, and the subcutaneous connective tissue only secondarily.

Dr. JACOBI then went on to say that according to some authorities, most, and to Cohnheim, all malignant tumors, occurring at any time of life, were the result of embryonic cells not undergoing their accustomed changes, and remaining behind in normally developed tissue; and if this theory was to be accepted, it would sufficiently explain the appearance of these malignant growths in early childhood. Furthermore, the fact that the bloodvessels were largely increased was no doubt the result of the embryonic tissue remaining; and these bloodvessels, it was to be noted, were not in a normal condition. He thought it probable that the occurrence of spontaneous thrombosis might explain the disappearance of the red spots and other phenomena noticed in the disease in question. On the whole, therefore, it seemed to him as if there was an arrest of the metamorphosis of embryonic tissue; and, if this were the case, he thought that in the treatment of this affection it might do good to increase the quantity of normal connective tissue, if possible, and thus fortify the parts against the further development of abnormal growths.

For this purpose, provided the supposition mentioned were correct, there were two remedies which suggested themselves as being specially indicated. These were, first, arsenic, and second—and better still—phosphorus. By the irritation caused by proper doses of these agents it seemed possible to excite a good, solid, normal nutrition in the tissues referred to. It was well known that phosphorus favorably influenced the normal growth of bone, and for some years past he had used it with satisfactory results in caries and other bone disease, finding it of special service in cranial rachitis. The phosphates or other compounds were of no value, and it was necessary to use phosphorus itself, administering it in oil or emulsion. It might be given in doses of one-hundredth of a grain, corresponding to one minim of the old oleum phosphoratum, twice a day, and its use should be maintained for a long period.

In conclusion, Dr. TAYLOR said that he thought these suggestions of the President very valuable and practicable, and that if he should meet with another case of the disease, he would institute a systematic course of medical treatment in accordance with them. At the same time, he thought the surgical measures to which he had referred in the paper were of decided benefit in controlling some of the more serious results of the disease; and, contrary to what might perhaps be expected, he had found that, as a rule, the tissues healed well after the removal of the new growths.

Recent Literature.

Nasal Polypus, with Neuralgia, Hay Fever, and Asthma in relation to Etmoiditis: By EDWARD WOKES, M.D., London. Philadelphia: P. Blakiston, Son & Co. 1887.

The chief object of this treatise is to discuss a disease which the author calls *etmoiditis*, and which he considers to be of preëminent importance, because if his conclusions concerning it be correct, it will place the more important affections of the nose on a sound pathological basis, and will enforce on their behalf a more radical system of treatment. The author applies the term *neurosis etmoiditis* to a special inflammation of the nasal tributaries of the ethmoid bone, and this, he contends, lends to the development of myxoma. He states that every case under his observation, whenever mucous polypus had been present, necrotic squames or spicules could be detected also. Three careful chapters are devoted to the elaboration of this theory, and a condition is described which undoubtedly exists in the nose. The statement, however, that all mucous polypi have their origin in a necrotic process of the structures constituting the spongy bones is fortunately not borne out in practice.

Treatment of Disease in Children, including the Outlines of Diagnosis and the Chief Pathological Differences between Children and Adults. By ANGEL MONEY, M.D., M.R.C.P., Assistant Physician to the Hospital for Sick Children, Great Ormond Street, and to the Victoria Park Chest Hospital. Philadelphia: P. Blakiston, Son & Co., No. 212 Walnut Street. 1887.

This volume, which is one of the "Practical Series," is stated by the author to be intended for the senior student and practitioner. The book is of convenient size for reference, and presents a much more rational method and outline of treatment in children's diseases than is usually met with in treatises devoted to pediatrics.

The text is, at times, somewhat unsatisfactory in that it does not fulfil the promise of that high standard of information which we are led to expect from the preface and introductory, as may be seen in the chapter on feeding, which will hardly satisfy the "senior student" in his investigations in this important branch of the subject, and will in places be found to be incorrect, especially where reference is made to the chemistry of human milk, as compared with cow's milk.

The chapter devoted to nervous diseases is an excellent compendium for study preparatory to the acquisition of any real knowledge of these important diseases, but is not otherwise of much practical value.

The book, as a whole, is disappointing, both from the bad division of the subjects, and its inaccurate and often misleading statements.

— A German pharmaceutical journal, remarking on the great frequency of fatal accidents from taking carbolic acid by mistake, states that these form 90 per cent. of all the fatal cases of taking the wrong medicine, and points out the great importance of always using poison bottles and poison labels for carbolic acid.

THE BOSTON
Medical and Surgical Journal.

THURSDAY, MARCH 1, 1888.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States and Canada; \$6.00 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 94 Boylston Street.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the "Manager of the Business Department," Medical and Surgical Journal, 94 Boylston Street.

Remittances should be made by money-order, draft, or registered letter, payable to

CUPPLES AND HURD,
94 BOYLSTON STREET, BOSTON, MASS.

A NATIONAL BUREAU OF HEALTH.

A HEARING was given at Washington on Friday, February 24th, by the Committee on Commerce of the House of Representatives, to persons interested in a bill now before Congress for the establishment of a Bureau of Health in the Department of the Interior.

This bill is identical with the measure brought to the attention of the last Congress and was at that time quite fully noticed in this JOURNAL, with approval; as then stated, it is probably all that can now be obtained from Congress, and has the very great advantage of an apparently undivided support on the part of the various State Health Authorities.

The American Public Health Association was represented by a committee consisting of Drs. Walcott, and McCormack with Medical Director Browne of the Navy, and also by Drs. J. S. Billings and G. M. Sternberg, of the Army, former presidents of the Association. Dr. McCormack also appeared in behalf of the conference of State Boards of Health, of which organization he is president.

They all spoke strongly in favor of the legislation proposed. The admirable work of the National Board of Health was noticed, and some of the influences, which had been most potent in its destruction, were alluded to. Dr. Hamilton, who bears the impressive title of Supervising Surgeon-General of the Marine Hospital Service, was the only person who appeared in opposition. He expressed the opinion that the work of the National Board of Health was of very little value, and stated that his own department now had charge of all that was doing by the General Government for the protection of the public health, and could do all that might hereafter be required in this direction.

The advocates of the bill did not hesitate to pronounce Dr. Hamilton's present work, as a public health officer, entirely unsatisfactory to the bodies represented by them, and seemed also to entertain the opinion that Dr. Hamilton might find his own time fully occupied by the discharge of his proper duties,

and the more so as he is at the same time in the practice of medicine at Washington and teacher in a medical school. He also has charge of such quarantine functions as are assumed by the General Government, and in these the present bill does not disturb him.

The contest seems therefore to be between an ambitious active man in place at Washington, skilled in the use of the political machinery of the capital, eager to increase the importance of his department, and the various health authorities scattered throughout the Union, and not easily combined for the purposes of an efficient representation at Washington.

There can be no doubt, however, that sooner or later a national health authority of generally satisfactory character must be created, and it will be a misfortune if it has to be created under the inevitable pressure of an invasion of cholera or yellow fever, because it will then be the hasty and timid creation of fear.

Dr. Robert T. Davis's legislative experience, his long and valuable service on the Massachusetts Board of Health, creditable both to himself and the State, give to his advocacy of this bill great strength and influence. So far as a presentation of the case on the floor of Congress goes, the prospects of success were never better; but the influence that secures legislative action rests with the medical profession of the country as a whole.

ANIMAL EXTRACTIVES AND THE PATHOGENY OF BRIGHT'S DISEASE.

At the meeting of the Paris Medical Society of the Hospitals, January 13th, Dr. Gaucher read a remarkable paper, which, while shedding some light on the pathogeny of chronic parenchymatous nephritis, and again bringing before the profession the rôle of extractives and poisonous "ptomaines" in the economy in health and disease, also calls attention to a possible source of danger in the too free use of animal food, and especially of meat extracts in certain morbid conditions.

The epithelioid form of Bright's disease, the "large white kidney," he believed to be of toxic origin, but the poison is generally generated in the organism of the patient. This poison is of a complex nature, being composed of divers extractive matters which result from the incomplete oxidation of azotized matters. Gaucher has performed many series of careful experiments on animals (guinea-pigs and hares), which, he thinks, prove the noxious action of these toxic principles on the kidneys. These experiments consist in introducing by subcutaneous injection into the organism of these animals, day by day for several weeks, a gradually increasing quantity of leucine, tyrosine, creatine, creatinine, of xanthine and hypoxanthine, in watery solution. The animal which is made the subject of this experimentation rapidly becomes albuminuric, and eventually dies; at the necropsy there is found an epithelial nephritis, of the

nature of the large white kidney. The accumulation of extractive matters in the blood may then, says Gaucher, through the elimination of these products by the kidneys, irritate the secreting epithelia and give rise to parenchymatous nephritis.

All these extractive matters in the normal state remain in small quantity in the circulation; but their production augments in many pathological states.

First in order come the diseases of the liver, which impede the transformation of azotized matters; and in affections of the hepatic parenchyma the formation of retrograde extractives augments in notable proportions, while there is diminution in the quantity of urea excreted. It is very probable that it is to the accumulation of the azotized *débris* of disassimilation in the blood that the frequency of albuminuria in cirrhosis of the liver is due. There is another disease in which the hepatic parenchyma is still more profoundly affected; namely, grave icterus. Now the nephritis of grave icterus is an epithelial nephritis which presents all the essential characters of the large white kidney. But the important fact in this connection is that in these especially malignant forms of jaundice there is exaggerated production of extractive matters, and a diminution in the figure of urea excretion which is lower than that observed in any other disease.

This excessive production of extractives is not limited to affections of the liver. In all chronic diseases there are disturbances of nutrition which must hinder the complete combustion of azotized materials. In accordance with the experimental evidence of the deleterious action of extractive matters on the kidney, one is led to the inevitable conclusion that the incomplete oxidation of the *débris* of disassimilation is the principal cause of the nephritis which are so frequently observed in the course of chronic diseases.

The influence of extractive matters on the kidney is of still wider extent; it may also manifest itself in the state of health. We know, in fact, that all the quaternary elements contain azotized substances in a state of incomplete oxidation; that broth notably has them, and concentrated broth especially; that the extracts of meat and the meat-powders contain a considerable proportion. Hence, the introduction of these alimentary substances, rich in extractive matters, may be deleterious, particularly to the kidney. This is especially the case when the kidney does not perform its functions well, and where the elimination of these toxic products is impeded.

Hence, then, the excessive introduction or the exaggerated production of extractive matters in the organism, or, even with a normal production, an insufficient elimination — such are, M. Gaucher thinks, the ordinary pathogenic conditions of the large white kidney.

Given these experimental data, and there result important therapeutic conclusions, on which M. Gaucher strongly insists. First of all, the danger of meat *bouillons*, beef extracts, etc., in nephritis. To

the nephritic, Gaucher says: "bouillon is a solution of poison." There is, he adds, in all diseases, and even in healthy persons, a danger from extracts of meat, from concentrated broths, from meat-powders, which, apart from the toxic mineral salts, and especially the salts of potassium which enter into them as ingredients, contain organic poisons, and even all those excrementitious principles whose noxious action has been alluded to. In all chronic diseases, and likewise in fevers, nutritive disturbances are constant; metabolism goes on incompletely; there is abnormal production of extractive matters. If, by the food, we add still more of these toxic substances to those which already exist in the economy, we expose the patient to a double risk, and one which is even greater from the fact that the lesion of the kidney is a new cause of accumulation through failure of elimination.

Such is the substance of the views propounded by M. Gaucher in his ingenious and ably defended thesis. Future experiment may confirm much of what he has advanced, but we fear that physicians will be loth altogether to relinquish confidence in meat extracts and meat powders on account of the possibly toxic and dangerous character of some of the ingredients which enter into their composition.

THE PAUPER INSANE OF THE STATE OF NEW YORK.

A BILL has just been introduced into the Legislature which has been prepared under the auspices of the State Charities Aid Association, by Prof. Theodore W. Dwight, of the Columbia College Law School, who is a member of the Association's Committee on the Insane, in behalf of State care for the pauper insane of the State of New York. It is designed to apply to the entire State, with the exception of the counties of New York, Kings, and Monroe, in which it is believed that further legislation is needed to meet the special condition of those counties; and the main provisions of the Act are as follows:

The State shall be divided into as many asylum-districts as there are State insane asylums in the State, and the President of the State Board of Charities, the State Commissioner on Lunacy, and the Comptroller of the State are to constitute a Commission empowered to define the boundaries of these several districts. Each of the State asylums for the insane shall receive patients, whether in an acute or chronic condition of insanity, from the district in which the asylum is situated, subject to the power of removal from one State asylum to another whenever in any of the districts the patients become too numerous for the accommodations provided, in which case those in excess may be transferred to another district, preference being always given to an asylum in an adjoining, rather than to one in a remote district. Furthermore, in case any insane person, his relatives, guardians, or friends, may desire that he may become an inmate of any State asylum situated beyond the

limits of the district where he resides, and there be sufficient accommodation there to receive him, he may be taken there in the discretion of the State Commission and the superintendent of such asylum, the expense of removal being borne by such relations or friends.

There shall be erected on the grounds of each State asylum a sufficient number of buildings of moderate size, each being designed to accommodate not less than twenty, nor more than two hundred patients, to meet the wants of the pauper insane of the district in which the asylum is situated; the plans for such buildings to be subject to the approval of the Commission mentioned above. The managers of each State asylum, in erecting these buildings, shall proceed upon the rule to limit the cost of the same so that it shall not exceed two hundred and fifty dollars *per capita* for the patients it is proposed to accommodate, and shall cause the buildings to be completed, if possible, within one year after this Act goes into effect. The buildings having been completed, the Superintendents of the Poor in each county within the district are to be notified to send all insane patients under their care to the State asylum, and it shall be the duty of all Town and County Superintendents sending a patient to any such asylum, before sending him, to see that he is in a state of perfect bodily cleanliness and is comfortably clothed, in accordance with regulations to be prescribed by the State Commissioner in Lunacy. The travelling expenses are to be paid by the State, and any State asylum may be required, when necessary, to send a trained attendant to bring a patient to the asylum.

There shall be a uniform charge by all State asylums to all counties included within this Act for care and maintenance of all insane patients, not exceeding \$1.50 *per capita* per week. The State Commissioner, whenever he may deem it necessary and expedient, by reason of overcrowding, and in order to prevent it, shall in his annual report to the Legislature recommend the erection of such additional buildings on the ground of any or all State asylums then existing as shall, in his judgment, provide sufficient accommodations for the immediate prospective wants of the insane, or, if he think it more expedient, shall recommend the establishment of an additional asylum or asylums. After the completion of the buildings provided for, it is the intent and meaning of this Act that no insane person shall be kept under county care within the counties embraced in it. The managers of each of the State asylums shall hereafter furnish the Comptroller, on or before the 15th day of September in each year, an estimate of the probable number of patients chargeable to the counties who will be inmates of their respective asylums during the year beginning October 1st next ensuing, and shall also furnish an estimate of the cost of maintaining persons so chargeable to the counties during the ensuing year. On the basis of these estimates the Comptroller shall, in his next annual report to the

Legislature, state his estimate of the deficiency to be provided for by the State for the support of such insane persons, after deducting the sum paid or to be paid by the counties at the rate of \$1.50 *per capita* per week. In addition to the counties of New York, Kings, and Monroe, this Act does not embrace the State asylums for insane criminals at Auburn and Matteawan, or the State asylum for insane emigrants on Ward's Island, in New York City. The concluding sections provide that the sum of \$500,000 be appropriated out of any moneys in the treasury not otherwise designated to carry the Act into effect, that all Acts or parts of Acts inconsistent with it are repealed by it, and that it shall take effect immediately.

There can be no question that the insane are much better cared for in the State hospitals than is possible, as a rule, in the county asylums, where they are usually treated, as far as circumstances will allow, simply as the other inmates of the poorhouses, instead of having the best medical treatment by alienist specialists, and the services of the highest grade of trained attendants, with the incentives to occupation, instruction, and amusement offered by the State institutions.

The bringing forward of this measure at the present time is said to be the result of a recent movement by the boards of supervisors in a considerable number of counties to secure special legislation permitting them to take charge of their own insane, instead of sending them to the State hospitals, as it is felt that to allow the counties to do this would be a retrograde movement, with a probability of a recurrence of the horrors of the poorhouse system of former years. It is intimated that there is more or less political influence at work in favor of this movement, and a strong and united effort will, therefore, be required to secure the passage of the excellent bill of the State Charities Aid Association. It seems reasonable to suppose, however, that this effort will be crowned with success, as for nearly fifty years the State has demonstrated its ability to care for the insane with the most satisfactory results in its finely equipped hospitals.

THE CASE OF HOFMANN, THE BOY PIANIST.

JOSEF HOFMANN, the boy pianist, has been withdrawn from the stage by his father. At the time of the medical examination of the boy in New York, some two weeks before, to which we have already made editorial reference, the father said that the lad was in excellent physical condition, that he committed his music to memory without effort, and that his public performances were only a diversion to him. Within a fortnight, however, the father's opinion on all these points underwent a complete reversal, and the manager was informed of the termination of the contract on account of the boy's physical inability to continue the performances. The results of the medical examination on the second occasion did not differ

materially from the first; namely, that the boy was not yet suffering very seriously from the confessedly trying hygienic conditions under which he had been placed. One physician even went so far as to say, according to the reports, that the lad would suffer if deprived from the recreation of playing in public. *Per contra*, it is stated on medical authority that he has suffered from enuresis during and after his performances, and at present he is said to have a temperature of over 100°, with a pulse of 97.

It is rather difficult to judge between the mildly conflicting medical testimony, to say nothing of the strongly conflicting testimony of those who look upon the boy chiefly from a commercial point of view. The lad's career is certainly far enough from what the hygienist would advise for a child of such an age, but his bodily health is probably not very different from what it was two weeks ago, when the parental interest coincided more closely with the managerial than at present. With a father on the one hand, and a manager on the other, neither of whom allows his business vision to be obscured by sentimental considerations, the boy needs an impartial medical tribunal, with something more, if possible, than merely advisory functions, to protect him from unpleasant trituration between the upper and nether millstones.

MEDICAL NOTES.

—The *Sanitary Era* has noticed for some time that about every fourth week — falling on one or the other side, or on both sides, of the contiguous borders of the calendar months — notably exceeds the average of the others in number of births. "Baltimore," it remarks, "which affords excellent returns for comparisons, again gives us for the first week of January 256 births, to an average of 137 for the following three weeks — an excess of 87 per cent. — and this is substantially the usual proportion, as we have hereinbefore noted. Do the medical authorities note such a rule as this? and how do they account for it? Is it connected with a prevalent relation of the catamenial period to the change of the moon? Kansas City, likewise, reports 71 births in the first week of January, against a following average of 38."

—The *Medical Record* says that Dr. Botkin, the physician to the Czarina of Russia, is said to have obtained his appointment by the exhibition of a little independence. He was called one day, so the story goes, to the Winter Palace, to prescribe for her imperial majesty, who was suffering from a cold. But the empress refused to disrobe sufficiently to allow him to auscult her chest, whereupon Dr. Botkin took his departure, saying that he didn't care to have anything to do with patients of that kind. The Czar was so pleased with this manifestation of spirit on the part of the physician that, instead of sending him to Siberia, he recalled him and appointed him special physician to the empress on a yearly salary of 100,000 rubles.

BOSTON.

—The twentieth anniversary of the foundation of the Washingtonian Home, was celebrated February 20th, with addresses by Hon. Joseph Story; by Dr. T. D. Crothers, of Hartford, Conn., who said that of the fifty inebriate asylums in the world, the Washingtonian Home was the first and the foremost; and by Dr. Albert Day, the superintendent.

—The annual report of the Boston Water Board, just issued, says that analyses by Professor Wood, of Harvard College, show that the Mystic supply appears to have been, through the year, of about the same quality as last year, but from the nature of its surroundings, the board not only can expect no improvement, but must anticipate a gradual deterioration. Basin 3, Sudbury River, Farm Pond, Lake Cochituate and the service waters are in better condition than in October, 1885 or 1886, and that of Chestnut Hill Reservoir better than in 1886. Referring to efforts on the part of Chelsea, Somerville and Everett to obtain control of the Mystic supply, the following remarks are made: "If they think, or can be brought to think, that the Mystic system would, if relieved of the necessity of supplying Charlestown, serve their purposes for a term of years, and that, with the Mystic Water Works in their hands, they could afford to take the chances of that term of years and of thereafter getting the Shawshen or some other supply to eke out their wants, we should be ready to recommend the City Council to take measures for the transfer of the Mystic Water Works to their ownership. We are ready to dissolve partnership on the most favorable terms. They have no claim whatever upon Boston, except for Mystic Water, and Boston has no other water to sell them."

—Rev. Dr. E. E. Hale, in behalf of the directors of the Seashore Home for sick children, at Winthrop, has issued an appeal to the public for \$10,000, with which to remove the old-fashioned country-house, hitherto used for the home, to one side of the lot, and to build a second house from plans prepared for the purpose. This addition will double the capacity of the home.

—A portion of one of the two new wards for contagious diseases, at the Boston City Hospital was at length opened for patients last week, and the cases of scarlet fever were transferred to it. The delay in getting these wards ready has been very great. It is as yet too soon to judge in all respects of the results obtained.

NEW YORK.

—The total receipts of the Hospital Collection for 1887 are now announced as \$50,408.10. The Distributing Committee of the Hospital Saturday and Sunday Association met on February 23d at the Mayor's office to make the annual distribution of the undesignated fund, which, after the deduction of expenses for the year, amounted to \$43,500. This is \$6,500 more than last year, and, owing to the withdrawal of the Presbyterian Hospital, and its share

going to the rest, it represents fully \$10,000 more. The institutions which receive the largest amounts are the following: Mount Sinai Hospital, \$7,550.56; St. Luke's Hospital, \$6,492.71; Society for the Relief of the Ruptured and Crippled, 5,200.68; German Hospital, \$4,735.28; St. Mary's Hospital for Children, \$2,425.68; Home for Incurables, \$1,997.93; House of Rest for Consumptives, \$1,716.73; House of the Holy Comforter, \$1,361.13; Montefiore Home, \$1,226.10. Of the designated contributions, St. Luke's gets \$1,102.81, St. Mary's \$803.69, and the German Hospital \$250.

—A serious outbreak of cerebro-spinal meningitis has occurred at the stables of the New York Riding Club on 58th Street, near Central Park, where are kept many valuable horses belonging to some of the wealthiest and most prominent citizens. An extended investigation of the other stables around the lower end of the Park has failed to disclose any other cases, and it is believed that the disease is due to local influences. The sanitary condition of the Club stables themselves is all that could be desired; but it is said that there is a large accumulation of sewage in some of the neighboring basements and cellars.

—At a meeting of the Section on Laryngology and Rhinology of the New York Academy of Medicine, held February 28th, Dr. Franklin H. Hooper, of Boston, read a paper on "Adenoid Vegetations in Children; their Diagnosis and Treatment"; which was followed by remarks upon "The Relation of these Growths to Middle Ear Disease," by Dr. Clarence J. Blake, of Boston. Among those announced to take part in the discussion were Drs. S. W. Langmaid, of Boston; J. N. Mackenzie, of Baltimore; T. R. French, of Brooklyn; and Beverley Robinson, F. H. Bosworth, R. P. Lincoln, D. B. St. John Roosa, Gorham Bacon, Samuel Sexton, H. D. Noyes, D. B. Delavan, and C. C. Rice, of New York.

PHILADELPHIA.

—Prof. R. A. F. Penrose has resigned from the faculty of the Medical Department of the University of Pennsylvania. It is rumored that a *concours* is to be held. If this is so, it is probably the intention to select the Professor of Obstetrics from among the younger men.

—The County Medical Society is holding very interesting meetings. Among the cases recently reported to this Society was one of removal of the kidney for bullet-wound, by Dr. M. Price. The patient was a girl fifteen years old, who received a gun-shot wound of the abdomen. The cavity was opened and the bullet traced to the right kidney, which bled freely, indicating a lesion of the vessels, and suggesting the propriety of nephrectomy. The patient recovered perfectly. The reporter would have preferred the lumbar section had he known that the kidney would have to be removed; nor would he have extirpated the organ had he not found it impossible otherwise to check the hemorrhage. At the same meeting, Dr. Frank Woodbury reported a case of pyo-nephrosis

following repeated attacks of vesical catarrh in a woman, thirty-five years of age, in which the right kidney was removed by lumbar incision by Dr. John H. Deaver, assisted by D. Hayes Agnew and the staff of the German Hospital. The patient perished on the fifth day. Dr. C. B. Penrose reported a case of a woman over fifty years of age, who suffered with malignant stricture of the descending colon. He made a laparotomy and removed the tumor, with ten inches of the large bowel, and sutured the ends of the gut together. A week later, when he reported the case, the patient was doing very well, and had had no bad symptoms. It was believed to be the first case in this country in which so large a portion of the large intestine had been excised. Dr. W. W. Keen subsequently exhibited a case of McEwen's operation for the radical cure of hernia, in which the hernia had returned, requiring the patient to wear a truss. He thought it instructive to report failures, as well as successes.

— Several cases of alleged cerebro-spinal fever were reported recently in the northern part of the city. The sickness occurred among the members of a sleighing-party, two of whom died. As this happened a fortnight ago, and no new cases are reported, it is believed that there may have been an error in diagnosis.

— The Philadelphia Dental College held its annual commencement on the 24th inst., and graduated a class of 119, which is said to be the largest class ever graduated by a dental school in this country or elsewhere.

Correspondence.

THE FOURTH YEAR DEGREE AT THE HARVARD MEDICAL SCHOOL, 1886-87.

HARVARD MEDICAL SCHOOL, February 27, 1888.

MR. EDITOR,—Will you kindly allow me a few lines to reply to a letter from Dr. E. Scott Dow, in reference to the fourth year degrees conferred in June last?

I can nowhere find on page 183 of the *Journal* the statement made by him, "that the fourth year class of 1886-87 numbered twenty-one, that eleven of them applied for the degree, and that five received it." There is a table showing the members of the fourth class, of the applicants for the degree, of the number who failed, and the number who received it *en route*. (The only error that is in this table was in the original, where the last figure should be 4 instead of 5.) It is a well-known fact that the applicants for the degree are not from the class of that year as it stands in the catalogue, a number always coming up out of course. And it is only by comparison of a number of years that a correct conclusion can be drawn as to the number of graduates in comparison with the number of students. If Dr. Dow had properly read the report as given in the *Journal*, he would have seen it was not intended to do any injustice to him, but simply to give information in regard to the general status of the fourth year students.

In regard to the catalogue class of 1886-87, the number of applicants for the degree was eight, of whom two received it, one *en route*, but recommended too late to appear in its proper place on the Commencement programme.

Very truly yours,

W. F. WHITNEY, M.D., Secretary.

METHODS OF MENSURATION.

DOVER, N. H., February 24, 1888.

MR. EDITOR,—I would call the attention of the profession to a simple, but not unimportant matter—to the proper method of measuring the sides of the thorax, or abdomen, for the purpose of determining the amount of unilateral enlargement in cases of pleuritic effusions, hepatic congestions, etc.

In a trial of a suit in the courts recently, the plaintiff claimed damages for injuries received on the highway, and two physicians testified as experts for the prosecution that there was an enlargement of one inch of the right side over the liver, as compared with the left side of the body. Three physicians testified for the defence that there was only one-half an inch difference between the two sides.

The difference in testimony was due to the different methods of measuring. One set of witnesses took separate measurements from the median line in front to the spinous processes behind on each side; whilst the other witnesses read off in both directions on the tape passed around the body, from the median line in front to the spinous processes behind.

The former method is open to criticism, since it contains three sources of error. The first source of error lies in the fact that there are two measurements to be taken instead of one, and in so doing there is greater danger of failing to start exactly on the *linea alba*, and of ending exactly over the centre of the spinous process. Secondly, the method does not insure measurements in the same horizontal plane; and, thirdly, the tension of the line may vary when each side is measured by itself, as in the last method.

Should we not have more harmony among witnesses if the first method only was followed, and should we not be more exact in diagnosis? Yours truly,

JOHN R. HAM, M. D.

[Undoubtedly it is to facilitate the method of measurement preferred by Dr. Ham that tapes have been devised, graduated and reading both ways from a common centre.—Ed.]

THE MURDOCK LIQUID FOOD HOSPITAL AND DR. H. O. MARCY.

BOSTON, February 24, 1888.

MR. EDITOR,—I ask the use of your columns to reply to Dr. H. O. Marcy's letter of the 16th, in relation to his connection with my Free Surgical Hospital for Women.

The letter is inaccurate in everything relating to facts, which I attribute to his short memory, and in correcting a few points I will show how he was connected with me and my hospital.

(1) His connection was not made by me, but by him through my head surgeon.

(2) He received no pay from me, but had and used the privilege of putting in private patients and receiving from them a fee for operations, nothing being charged or received by me in any case for board or attendance.

(3) We never had any disagreement until I refused to give him the control of my Gainsboro' Street Hospital, and then it came from him.

I quote from his letter of July 21, 1887 concerning displacement of Dr. Packard, who had been with me three years.

"The only misgiving in carrying this into effect, may be your obligation to Dr. Packard, a gentleman whom I very much like. If you think you had better do this, and if necessary indemnify him for any obligation you feel you may owe him, I am yours at command upon the conditions previously considered. I need not assure you that you have my best wishes in your good work, and that my relations with you have been to me highly satisfactory."

The other condition referred to is the incorporation of the hospital, or the appointment of a Board of Directors; to this I assented and the board was selected but not organized, as he was not satisfied with this alone.

Again, July 25, 1887: "I would wish for no more pleasant personal relations than have been between us from

the beginning, and should be glad to avail myself of the privilege of sending patients to you so long as I may be permitted. With the very highest considerations, believe me,

Very respectfully, HENRY O. MARCY."

Since that date he has sent me about two patients monthly.

I cannot see where I have compromised Dr. Marcy. My hospital on Huntington Avenue, is open to the inspection of the profession, under the sanction, and subject to the criticism of the proper authorities of the Massachusetts Medical Society. Before accepting the position of surgeon to my hospital, Dr. E. W. Cushing visited Natick, Worcester and Springfield, to consult with the chairman and senior members of the Committee on Ethics and Discipline of that Society. By their advice the whole matter, including the relations of the medical officers of the hospital, was submitted by Dr. Cushing in writing to the Committee on Ethics and Discipline. From its answer, received after a meeting of the council had intervened, it was decided to be a proper and honorable thing for a member of the Massachusetts Medical Society to hold a position as surgeon in my hospital. I enclose a copy of this correspondence.

By this correspondence, which was made with my knowledge and assent, I became bound to receive with respect any suggestions emanating from the Committee of Ethics and Discipline, in case my hospital should in any way merit its censure. I promised Dr. Cushing never to put him, nor his consultants or assistants in any position which should merit such censure. I never have done so, and I have no intention, or wish to do so. All this Dr. Marcy knew when he came here, and what he says about any other understanding, I must attribute to a confused or inaccurate use of language on his part.

The good work which has been done in my free hospitals this last year, being over five hundred operations—free as far as I am concerned—ought to entitle me to the respect of the profession, and all who visit me accord it to me.

I certainly was liberal in trying to remove from the mind of Dr. Davis, the president of the American Medical Association, any injury which Dr. Marcy's reputation might have suffered, by being connected with my hospital, as I gave Dr. Marcy authority to invite said president with a committee appointed by him, to visit Boston to inspect my hospital and I would pay the bills, and he should act on their instructions after the visit, not before, as they had no right to give advice without knowledge. This offer was declined by Dr. Marcy.

In closing, I would say my hospital on Gainsboro' Street was organized before Dr. Marcy came into the Huntington Avenue Hospital, and that there is no professional connection whatever between the surgeons of two hospitals, and that since he left me the usefulness of the regular hospital has increased, as the number of patients has increased, and these are sent in by physicians in most cases. To accommodate all these patients I have added two wards to the regular hospital. Moreover, many eminent physicians who personally were indifferent or critical, now send patients here and are present at operations. In point of fact, Dr. Marcy must have forgotten that he operated here on Mrs. G., on September 17, 1887, and that he was quite officious in inviting his friends here, and in sending in and showing his cases, when operations were performed here on September 19, 1887, by a distinguished foreign surgeon, in presence of some of the most eminent medical men of New York and of Massachusetts.

Yours respectfully, ALBERT L. MURDOCK, Proprietor.

REPORTED MORTALITY FOR THE WEEK ENDING FEBRUARY 18, 1888.

Cities.	Estimated Population.	Reported Deaths in each.	Deaths under Five Years.	Percentage of Deaths from

Deaths reported 2,693; under five years of age 941; principal infectious diseases (small-pox, measles, diphtheria and croup, diarrhoeal diseases, whooping-cough, erysipelas and fevers) 363, acute lung diseases 523, consumption 366, diphtheria and croup 143, scarlet fever 57, measles 38, typhoid fever 33, diarrhoeal diseases 29, cerebro-spinal meningitis 13, whooping-cough 13, erysipelas 11, malarial fever 11, puerperal fever 10, small-pox four, typhus fever one. From typhoid fever, Philadelphia 15, New York four, Pittsburgh three, Baltimore, Lowell and Fall River two each, Brooklyn, Nashville, Lawrence, New Bedford and Holyoke one each. From diarrhoeal diseases New York 12, New Orleans five, Philadelphia four, Brooklyn and District of Columbia three each, Boston and Cambridge one each. From cerebro-spinal meningitis, New York seven, Boston two, Baltimore, District of Columbia, Milwaukee and Worcester one each. From whooping-cough New York six, Boston two, Philadelphia, Baltimore, Pittsburgh, Milwaukee and Salem one each. From erysipelas, New York four, Philadelphia two, Brooklyn, Baltimore, Boston and Cambridge one each. From malarial fever,

New York seven, Brooklyn two, Baltimore and New Orleans one each. From puerperal fever, Brooklyn three, New Orleans Pittsburgh and Milwaukee two each, Boston one. From small-pox, Brooklyn four. From typhus fever, New York one.

In the 28 greater towns of England and Wales with an estimated population of 9,339,773, for the week ending February 21st, the death-rate was 21.9. Deaths reported 3,453; infants under one year of age 872; whooping-cough 248, scarlet fever 75, fevers 52, diphtheria 42, measles 35, diarrhoea 33, small-pox (Sheffield 17, Leeds and Bristol one each.) 19.

The death-rates ranged from 13.4 in Bradford to 32.2 in Plymouth; Birmingham 17.0; Blackburn 25.9; Hull 18.1; Leeds 19.5; Leicester 21.3; Liverpool 18.4; London 23.1; Manchester 27.3; Nottingham 18.8; Sheffield 22.1; Sunderland 20.2. In Edinburgh 19.5; Glasgow 26.2; Dublin 29.9.

The meteorological record for the week ending February 18, to Boston, was as follows, according to observations furnished by Sergeant O. B. Cole, of the United States Signal Corps:—

Week ending Saturday, Feb. 18, 1888.	Barom- eter.	Thermometer.				Relative Humidity.				Direction of Wind.		Velocity of Wind.			State of Weather. ¹			Rainfall.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM FEBRUARY 18, 1888, TO FEBRUARY 24, 1888.

VOLLUM, EDW. P., surgeon and lieutenant colonel. Granted leave of absence for four months, with permission to go beyond sea and to apply for an extension of two months. S. O. 41, A. G. O., February 20, 1888.

GRUBNER, E. F., captain and assistant surgeon. Granted leave of absence for one month and twenty-one days. S. O. 41, A. G. O., February 20, 1888.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE UNITED STATES MARINE-HOSPITAL SERVICE, FOR THE THREE WEEKS ENDING FEBRUARY 25, 1888.

WARDEN, EUGENE, passed assistant surgeon. Relieved from duty at Marine Hospital, Chicago; ordered to Marine Hospital, Mobile, Ala., February 16, 1888.

NORMAN, SEATON, assistant surgeon. Relieved from duty at Marine Hospital, New York, to assume charge of the service at Evansville, Ind., February 6, 1888.

WILLIAMS, L. L., passed assistant surgeon. Promoted and appointed passed assistant surgeon from February 10, 1888. February 23, 1888.

COBB, J. Q., assistant surgeon. Appointed an assistant surgeon February 21, 1888. Assigned to duty at Marine Hospital, Chicago, Ill., February 25, 1888.

STONE, J. B., assistant surgeon. Appointed an assistant surgeon February 21, 1888. Assigned to duty at Marine Hospital, New York, N. Y., February 23, 1888.

CONDUCT, A. W., assistant surgeon. Appointed an assistant surgeon February 21, 1888. Assigned to duty at Marine Hospital, Chicago, Ill., February 23, 1888.

SOCIETY NOTICES.

BOSTON SOCIETY FOR MEDICAL OBSERVATION.—The regular meeting of the Society will be held at the Medical Library, 19 Brimley Place, on Monday evening, March 5, 1888, at 8 o'clock. Readers: Dr. Knight, "The Selection of a Climate for Patients with Pulmonary Tuberculosis." Dr. Bundy, "One, Possibly Two, Cases of Graves' Disease."

CHARLES P. STRONG, M.D., Secretary.

SUFFOLK DISTRICT MEDICAL SOCIETY. SURGICAL SECTION.—There will be a meeting of this Section on Wednesday evening, March 7th, at 8 o'clock. Dr. O. K. Newell will read a paper on "The Surgical Use of Hebra's Continual Bath or Water-Bed." Dr. M. H. Harrington will report a "Case of Nephroptosis." Dr. G. W. Gay will present a communication on the "Treatment of Fractures of the External Condyle of the Humerus." Dr. S. J. Mixer will demonstrate a new method for removing powder grains from the face.

G. H. MONKS, M.D., Secretary.

RHODE ISLAND MEDICAL SOCIETY.—The usual quarterly meeting will be held in Lyceum Hall, 52 Westminster Street, Providence, on Thursday, March 8, 1888, at 10 o'clock, A.M. Paper by Dr. A. H. Harrington, on "Acute Ascending Paralysis." Dr. S. Oscar Myers will report a "Case of Belladonna Poisoning." Dr. Byron Whitford a "Case of Skin Disease in a New-Born Infant," and Dr. W. F. Morrison a "Case of Puncture of the Heart," with exhibition of the patient. Dr. W. J. McCaw, curator of the museum will exhibit specimens of interest.

W. K. WHITE, Recording Secretary.

H. G. MILLER, President.

APPOINTMENTS.

Drs. Edward Reynolds and Charles W. Townsend have been appointed Physicians to Out-patients in the Boston Lying-in Hospital.

BOOKS AND PAMPHLETS RECEIVED.

Cystitis in the Female. By Henry O. Marcy, A.M., M.D., LL.D., of Boston, U. S. A. President of the Section of Gynecology, Ninth International Congress; late President of the American Academy of Medicine, etc. Reprint. 1887.

Hysteria and its Relation to Diseases of the Uterine Appendages. By S. C. Gordon, M.D., of Portland, Maine. Reprint. 1886.

Agnosticism, Based on Physical Science. Second (Revised) Edition. By Alex. W. Stein, M.D., Visiting Surgeon to Charity Hospital, Professor Visceral Anatomy and Physiology, New York College of Dentistry, etc. 1888.

A Case of Extra-Uterine (Infant) Pregnancy. Rupture at Three Months; Laparotomy; Recovery. By S. C. Gordon, M.D., Portland, Me., Lecturer on Diseases of Women in the Portland School for Medical Instruction, Surgeon to the Maine General Hospital, etc. Reprint. 1888.

Original Articles.

THE MALARIAL INFLUENCE OF THE TYPHOID FEVER OF 1887 IN BOSTON.¹

BY EDWARD N. WHITTIER, M.D.,

Assistant Professor Clinical Medicine, Harvard Medical School; Visiting Physician Massachusetts General Hospital.

In complying with the recent request of our President to prepare a paper for this evening, I found in the subject selected unexpected difficulties: difficulty in dealing with a relatively novel theme, difficulty in arranging the material, so that forces, sometimes considered to be at variance, should appear, as it seems to me they are, coöperative, and difficulty in so condensing facts, as to place before you those facts upon which I have based my opinion in the time and within the limits at my disposal.

I would ask your particular attention to the charts, and to the synoptical, selected, illustrative cases, and I desire to acknowledge the very valuable assistance of Dr. Jacobs, recently senior house-physician, Massachusetts General Hospital, in their preparation. The charts are intentionally so arranged as to place before you: first, the schematic representation of the temperature curve in typhoid fever after Liebermeister; next, a chart from a case not subject to any other than the influences present at the time, in Boston, to modify the course of typhoid fever; third, a chart from the case of a man who had previously to the recorded history of modified typhoid acquired intermittent fever in a malarious region; fourth, a chart from the case of a patient, previously healthy, acquiring typhoid fever in a locality until recently free from malarious influences, and the chart of remittent fever after Bemiss, and of tertian ague after Strümpell; these last, as well as the first one, are for the purposes of comparison, and to aid in the demonstration of the relation between the causative and combined influences (typhoid and malarial) and the effect which I designate as the malarial influence on the typhoid fever of 1887 in Boston.

Permit me to call your attention anew to the fact, long since demonstrated, that in the combined typhoid and malarial fevers, each element modifies the other: for instance, periodicity is less distinctly marked, and the influence of anti-periodic remedies greatly diminished by the co-existing typhoid element.

Entering upon a term of service at the Massachusetts General Hospital on the 1st of November last, at a time when the annual outbreak of typhoid fever was already well advanced, I was at once deeply impressed by the wide variations presented by the bedside charts of temperature, pulse and respiration, from those made familiar by an experience of many years, and it was the strong evidence afforded by a study of these variations, convincing me of a co-existing and modifying influence of an unaccustomed form in the typhoid disturbances of last year, which has led to the preparation and presentation of this paper.

If we follow the chronological order of the local literature on the subject of intermittent fever in Massachusetts, we shall also follow quite closely the geographical order of its progress or development in the last half century; for in 1834, Dr. Holmes wrote the Bolyston Prize Essay on "Facts and Traditions Respecting the Existence of Indigenous Intermittent

Fever in New England," in which he plainly sets forth the frequency of the disease in the lower towns of the Connecticut valley, and its relative infrequency in the eastern sections of the State.

In 1880, Dr. Adams, of Pittsfield, prepared the admirable paper to be found in the "Supplement to the Second Annual Report of the State Board of Health, Lunacy and Charity," and by careful analysis of the facts, gathered by him, with infinite labor and pains, demonstrated the eastwardly advance of the disease, and if I may use the expression, located the head of the column in strong force, and well entrenched in the valley, and on the hillsides of the Housatonic river, and pickets and outpost stations in Hampden, Worcester, and Middlesex counties.

In 1886, Dr. Z. B. Adams, of Framingham, read at the annual meeting of the Massachusetts Medical Society, his paper on "An Epidemic of Malaria in Eastern Massachusetts," with particular description of the outbreak of 1885, in Framingham. This epidemic included two hundred or more cases of varying degrees of severity, generally of the tertian type, and Dr. Adams's valuable contribution to the literature of the subject, presents the views of the best observers, while at the same time he places on record his observations and statistics of an epidemic of malaria in an unaccustomed region, and states, "intermittent fever seems to have been on a hostile march through New England, generally in a north-easterly direction, during a period of fifteen years, until at last it has reached the geographical centre of Eastern Massachusetts."

During 1887, Natick, Waltham and the neighboring towns, have been invaded in strong force, and the disease advancing through the valley of the Charles River, has levied a heavy assessment upon the Newtons, Riverside and Auburndale, and has forced Cambridge to enroll a large contingent.

From information in my possession I have reason to believe that within the limits just indicated, there have been at least three hundred and fifty cases of tertian ague during the past twelve months.

In 1876, Dr. Woodward read before the International Medical Congress in Philadelphia, his paper, now classical, on what he termed typho-malarial fever, and he cited of uncomplicated typhoid fever, occurring during the war, 80,272 cases, with a mortality among white troops of 35.89%, among colored troops of 55.68%; while of the compound disease which he designated as typho-malarial, 57,400 cases are cited with a mortality among white troops of 8.13%, among colored troops of 17.37%, and he demonstrated beyond cavil the conjoint and modifying existence of each factor, the malarial as well as the typhoid, and secured for the term he employed, a permanent position in medical nomenclature. Whatever objections may be raised to this compound prefix, typho-malarial, and the objections are many and various, it nevertheless must be admitted to express tersely, comprehensively, and conveniently, a positive association of two distinctly different diseases.

I concede that in localities constantly malarious, that influence overrides and at times quite nearly masks, the typh-element, and that it is by reason of this well-recognized fact that Woodward's conclusions have been so strongly contested, even so late as at the meeting of the Association of American Physicians last year, when Professor Atkinson, of Maryland, in a very able paper, deplored the confusion in inaccu-

¹ Read before the Boston Society for Medical Improvement, February 13, 1888.

racy which had increased of late from a too ready acceptance of Woodward's views; but with all this, this paper has but little to do, for I am quite well satisfied that the class of cases included in Dr. Woodward's tables, varies in important respects from those malarial modifications of typhoid fever now occurring in Eastern Massachusetts, and that the discussion which followed the presentation of Dr. Woodward's paper, and preceded the adoption of his term, typho-malarial, and its qualifying definition, can be appealed to to furnish evidence of the differences in the degree of preponderance of the concurring elements, then and there, as compared with those of to-day and here — then and there malarious, now and here typhoid.

I have traced with extreme care the malarial movements eastward, until I am satisfied that it has effected an important change in the symptomatology of typhoid fever in Boston and vicinity, and that an etiological factor of much significance has been recently added to modify the course of our chief continued fever; and that in this vicinity it should now be clearly recognized that while the typh-elements of necessity predominate, and must continue to predominate, malaria can and does not infrequently nor feebly modify the course of typhoid fever, and that we now have to deal with a disease, which is the resultant of the factors, which, when acting separately, can produce either typhoid or malarial fever.

The typhoid fever charts at the Massachusetts General Hospital for the years 1885-86, are chiefly of value as illustrations of the therapeutics of modern antipyretics; they are not important in the sense of contributing to our knowledge of the natural history of the disease.

But in the year 1887, the opinion which prevailed, the reactionary opinion, if I may so express it, relative to the necessity as well as the propriety of employing the modern synthetical compounds for diminishing heat-production and reducing temperature, resulted in their comparative disuse, and the charts which I make use of in connection with this paper, may be accepted as those of typhoid fever, unmodified except by the influences which I designate as malarious; they are derived from a considerable number of cases quite closely related and uniform in symptoms, a class of cases which I believe to be increasing in this community and demanding the thoughtful consideration of every practitioner of the art and science of medicine, desirous above all things of surrounding his patients with every safeguard, and the highest degree of protection.

One interesting fact should not be lost sight of, and it is this, there is good reason for concluding that the malarial modification of typhoid fever is most conservative, for it appears to have been the opinion of the earlier observers of the outbreaks of malarial fever in Western Massachusetts, that the malarial diminished not only the force but in a marked degree the frequency of the typhoid fevers.

Admitting the correctness of Dr. Woodward's tables the mortality in uncomplicated typhoids of 35.89% were reduced by the malarial complication to his "typho-malarial" cases, to 8.13+%, or to express it in another way, the mortality among white troops caused by uncomplicated typhoid was $4\frac{1}{2}$ times greater than the same disease when combined with malarial influences, and therefore I think there is warrant for the opinion that the typh-process is so modified by the malarial

influence as to be stripped of some of its most dangerous features. The disease under consideration in this paper is primarily and persistently typhoid, by some described as a new hybrid of old and well-known pathological conditions, in which the exact train of symptoms is as variable as the degree of preponderance attained by each of the concurring elements.

It is an endemic infectious fever, whose pathology finds constant expressions in lesions of the intestinal mucous membrane, of Peyer's patches, enlargement of the spleen and secondary changes in the mesenteric glands; a fever whose natural course varies from that of typhoid fever, because it is modified by the earth-born poison, the miasm of malaria with which its initial cause blends.

The strong diagnostic points are: that typhoid fever of considerable duration is modified in its history and has added to it chills of varying degree of periodicity, generally tertian in type however, not followed by evidences of inflammation either thoracic or abdominal but accompanied by temperature changes of wide range, with distinct intermission, and requiring active measures to prevent collapse, because of a tendency in that direction, in degree proportionate to the co-existing exhaustion, induced by the pre-existing ante-dating typhoid fever process.

I believe that its purest type will be found in regions where malarious fevers are non-indigenous, inconstant and infrequent, subject to cyclic invasions, or for instance, in Massachusetts, 1798, 1836, 1880-87, a periodicity of about forty years. So that during the century in which it has been so well recorded here, it has come up out of the South, from beyond the isothermal line of 70° F, mean summer temperature where malaria is conceded to be endemic, and advancing northward, bending slightly westward into the valley of the Housatonic, then gaining ground to the east until at last moving down the valley of the Charles River, it has reached its easternmost point and its limit on the shores of Massachusetts Bay.

CASE I. Entered November 28, 1887. Male, aged twenty-eight, single. Born at Prince Edward's Island. Lived for several years in Eastern Massachusetts, Danvers, Worcester and Somerville. For past seven months worked in Massachusetts General Hospital, as ward-tender to the medical side.

Previous habits and health excellent. Symptoms of illness began three or four days previous to entrance, and consisted of anorexia, headache, backache, pain in limbs, dryness of lips, mouth and throat; prostration, general malaise, feverishness, restlessness, and sleeplessness at night, slight cough, without expectoration, abdominal pain and tenderness, constipation.

Examination. Skin hot and dry; face flushed; lips and tongue dry, latter with brownish coat; pulse good strength, rather bounding; lungs, heart, liver, negative; abdomen slightly distended, generally resonant; tenderness and gurgling in right iliac fossa; few rose spots, scattered; spleen not felt; area splenic dulness, 3 x 4 inches; urine negative.

Through the remainder of the first and during the second week, headache and backache persisted; constant complaint of pain and tenderness in right iliac region, and upward and transversely along course of ascending and transverse colons; constipation; restless and sleepless at night; mind clear; tongue dry, thick brown coat; new rose spots; abdomen more dis-

tended, tympanitic; splenic dullness increased to 4 x 6 inches.

In third week. Patient much weaker; mind rather dull; headache gone; abdominal pain and tenderness as before; some cough, with frothy mucus expectoration; constipation; pulse soft, slightly dichrotic; few medium and fine moist râles at bases posteriorly; rose spots fading; no new ones; distension of abdomen as before; one dejection with a trace of blood.

In fourth week. Improvement great; abdominal pain, tenderness and distension gone; râles in chest diminished; tongue cleaning; pulse good; splenic dullness, 2 x 4 inches.

December 20th. Feeling of prostration; pain under left scapula; sudden rise in temperature; no physical signs to account for it.

December 21st. Feeling well again.

In fifth week. Convalescence apparently established till evening of December 25th, when made complaint of chilliness, headache and general malaise, at 11 P.M., pronounced rigor for three-quarters of an hour, followed by fever. Given quinine, grs. ii, every two hours.

December 27th. Chill at 3 A.M., not quite so severe as before.

December 28th. Chilly sensations at night; no rigor; ringing of ears. Quinine reduced.

In following weeks. No more chills nor chilly sensations, full improvement, and discharge from hospital.

CASE II. Entered August 17, 1887. Male, aged twenty-four, married. Born at Troy, N. Y. Previous health good, except for intermittent fever nine years before in New York State.

Symptoms of illness began about two weeks previous to entrance, and consisted of anorexia, general malaise, deafness, epistaxis, diarrhœa.

Examination. Fairly nourished; pale; nervous; somewhat confused; muscular tremors of lips, tongue and hands; tongue dry and coated; slight cough; lungs negative, except for few fine scattered moist râles; heart negative; abdomen distended; numerous rose spots; right iliac gurgling; spleen not felt; splenic dullness, $3\frac{1}{2}$ x 7 inches; urine negative.

In third week (first in hospital). Patient restless and delirious; diarrhœa; rose spots present; abdomen distended; high evening temperature.

In fourth week. Improvement; less diarrhœa; less abdominal distension; rose spots fading.

In fifth and sixth weeks. Rise in temperature; diarrhœa increased; more restless and delirious; pulse rapid, soft, somewhat dichrotic; ataxia marked; evidences of cardiac complications (endocarditis); abdominal tympany; abundant new crop of rose spots.

In seventh week. Some improvement; less diarrhœa; less violent delirium; the rose spots fading.

evidences of increased size of liver. Quinine, nine grs. per day given.

September 23d. Chill.

September 26th. Chill.

In ninth and tenth weeks. Continued improvement in general condition. Physical signs as before.

September 29th. Severe chill.

October 7th. No chill since 29th ult. Quinine omitted.

October 8th. Chill; enlarged spleen persists.

October 9th. Chill. Quinine resumed, twenty-four grs. per day.

In eleventh and following weeks. Convalescence established; flesh and strength returning.

October 17th. Chill. Quinine thirty grs. per day.

October 18th. Severe chill.

October 20th. Quinine increased to thirty-two grs. per day. Ringing of ears in a day or two, and quinine gradually reduced. Nor further chill. Improvement rapid and uninterrupted.

November 10th. Discharged well.

CASE III. Entered October 7, 1887. Female, aged twenty-one, single. Born in Prince Edward's Island. Lived for past year in Cambridge.

Previous health excellent. Deaf for two years. Symptoms of illness began four days previous to entrance, and consisted of chilly sensations; feverishness, severe headache, anorexia, diarrhoea, pain in back and limbs, restlessness at night, tired and run down feeling. Catamenia present for three days.

Examination. Fairly nourished; face flushed, tongue—thin, white, moist coat; chest negative; abdomen slightly full, resonant; gurgling in both iliac fossae; no tenderness; no rose spots; spleen not felt; splenic dulness, $2\frac{1}{2} \times 4\frac{1}{2}$ in.; urine negative.

In second week. Patient very delirious at night; dull and stupid by day; several rose spots; slight tenderness in iliac regions; profuse diarrhoea; abdominal distension; considerable headache.

In third week. Cessation of diarrhoea; less abdominal distension and tenderness; rose spots fading; mind clearer; no delirium at night; very comfortable; sleeps large part of time.

In fourth week. Patient quiet; no complaint; pulse good; tongue cleaning; no signs in chest; abdominal distension and tenderness gone; splenic dulness normal; somewhat more deaf. Examined by Dr. J. O. Green, who made diagnosis: "Evidently case of old deafness, with infiltration of tympanum and labyrinth accompanying typhoid."

In fifth week. Apparently doing well, until on November 3d and 6th, complaint of headache, feverishness, and chilly sensations, accompanied by sudden rise in temperature. No physical signs, either thoracic or abdominal, explanatory.

In sixth and seventh weeks. Patient weaker; some vomiting; pulse not so strong; slight cough; few, fine moist râles at bases posteriorly; no other abnormal physical signs.

November 8th. Again chilliness, with elevations of temperature.

November 10th. At 7.45 A.M., pronounced chill for one-half hour; temperature 105.2° ; sweating followed. Quinine, grs. ii, every two hours given. Chill repeated at 10.45 P.M.

November 12th. Severe chill at 7 P.M.

November 15th. Extreme rigor at 3 A.M.; patient delirious; temperature 107° in rectum. Antefebri-

grs. ii, given. Two hours later, temperature 106° , antefebri, grs. ii, repeated. In next twelve hours, fall in temperature of 13° , with profuse sweating, prostration and collapse; semi-consciousness; stimulants, heaters, rubbing, etc., employed.

November 16th. Temperature back to normal this P.M.

November 17th. Chill, much less severe; evidence of cinchonism. Quinine reduced.

In eighth and following weeks. Convalescence only interrupted by two slight chills.

November 23d and 24th. Steady improvement afterward, and final recovery and discharge from hospital.

A METHOD OF ESTIMATING ADDUCTION AND ABDUCTION OF THE LEG IN HIP DISEASE.

BY ROBERT W. LOVETT, M.D., OF BOSTON.

THE presence of adduction or abduction of the diseased limb in hip-joint disease is one of the commonest and most troublesome of the complications of that affection, and the estimation of the amount of malposition present is a matter of much importance, both during the acute stage of the disease, as an index of the progress of the case, and after the arrest of the disease, where a return of the adduction and a consequent increase of the limp and discomfort is always to be feared. It has been customary to calculate in degrees the amount of malposition present either by a rough guess or by the use of the goniometer, an instrument not often at hand, and always clumsy and inaccurate.

The following article is a purely mathematical deduction from certain evident anatomical relations, by which it has been possible to construct a simple and practical table for working purposes in the estimation of the amount of this malposition. The method is, in a word, the estimation of the angle of malposition of the diseased limb by the varying differences between what we may call the real and the apparent shortening of that leg. Real shortening is the term to be applied to the difference in the length of the legs, measuring from the anterior superior spines of the ilium to the external or internal malleoli—the common measurement.¹ Practical shortening will be used to denote the difference in the length of the legs when the measurement is taken from the umbilicus to the malleoli while the patient lies straight, with the legs parallel,² and represents, of course, the amount of shortening which will be present when the patient stands or walks, for the legs must then necessarily be made parallel, even if the pelvis has to be tilted to make them so. Practically, real shortening may be the same as apparent shortening; it may be greater, or it may be less, and I had noted that it varied in proportion to the amount of deformity present, but I was unable to express this variation as degrees of malposition, and I am wholly indebted to Mr. G. L. Kingsley, of the Harvard Medical School, for the mathematical assistance which has made it possible to work out and prove the practical usefulness of the method.

When the patient lies straight and neither leg is adducted, it hardly needs mathematical proof to show that the real shortening is equal to the practical short-

Fig. III.

ening (Figure I). Here E and C represent the malleoli, D and B the anterior superior spines, and A the umbilicus. A glance shows that the difference in the length of AE and AC will be the same as the difference between DE and BC (both differences in this case being zero) so long as the pelvis is square.

The mathematical proof of this is: Since FE and GC are parallel in this case, and $FD = GB$ (FG being parallel to DB) and $FA = AG$, and AFE and AGC are right angles,

$$\sec. GAC = \frac{AG}{AC}$$

$$\sec. AFE = \frac{AE}{AF}$$

$$\tan. GAC = \frac{GC}{AG}$$

$$\tan. AFE = \frac{FE}{AF}$$

$GC = AC \cdot \sin GAC$ $GC - FE = AC \cdot \sin GAC - AE \cdot \sin AFE$
 $FE = AE \cdot \sin AFE$
 that is, practically differing only by the difference in the sines of the angles ACG, and AED and since the angles in the class of cases under observation are very nearly equal, the error is not appreciable, for the maximum error would be 0.03 inches.

If, however, one leg is held adducted or abducted by muscular spasm or ankylosis, the pelvis must necessarily be tilted when the legs are made parallel, as in standing or walking, and the state of affairs is represented by Figure II. It is obvious that now the distances from B to C and D to E are the same as before, whereas AC has grown very much longer than AE; the practical shortening of the leg DE has, in fact, become greater than the real shortening because the leg is adducted. It is, moreover, evident that this must vary in proportion to the amount of adduction and consequent pelvic tilting, for, by the latter, one leg must be carried up and the other down, while the umbilicus remains stationary, so that as the pelvis tilts more and more, AE grows shorter and AC longer.

It is not quite correct practically, to assume that $DE = BC$ in figure II, for Dr. Halstead* has pointed out that a leg in adduction has not the same real length when measured from the anterior superior spine to the malleoli, as the same leg in the normal position or abducted, but the difference is to be expressed in millimetres and practically does not enter into this method as an error, it is too small to be of any account.

Of course it is not assumed that the anterior superior spines are the same distance apart as the acetabula, but the practical centre of motion of the leg in adduction and abduction is not at the acetabulum but outside of it, as can easily be seen in the skeleton. This is of course on account of the angle that the shaft makes with the neck of the femur. So far as could be determined, it was well enough represented by saying that it was in the lines of the anterior superior spines. The only inaccuracy likely to be caused by this, would be

possibly in the adult female pelvis where the flare was extreme and even here the error would be small and of little account.

The problem was to make this variation express in degrees the angular deformity of the adducted or abducted leg which caused this pelvic tilting; and for working purposes Figure III had to be constructed, where the original position of the pelvis is represented by dotted lines, and the tilted pelvis by heavy lines. Of course, a working triangle must be found, and such a triangle is LFB, for FLB is the angle to be measured, for it is the angle of pelvic tilting which is equal to the lateral variation of the diseased leg from the normal.

For, letting DB = pelvis in new position, and GF = pelvis when square, DE = position of leg, and DM = position leg should have if still at right angles to pelvis, and M'DF = adduction angle.

$\angle ALG = 90^\circ$, $\angle DLM = 90^\circ$, $\angle EDL = \angle L$ (since AN and DE are parallel and cut by the line DL).

$$90^\circ = \angle ALG = \angle ALD + \angle DLG$$

$$90^\circ = \angle DLM = \angle LDE + \angle MDE$$

$\therefore \angle DLG = \angle MDE =$ adduction or abduction angle.

Now of this right-angled triangle, LFB, two sides are known: LB, which is equal to half the distance between the anterior superior spines of the ilium; and BF, which is equal to half the difference between the real and apparent shortening. The pelvis tilts, and one foot is carried up and the other down, and the practical shortening is the sum of these excursions.

First, when the legs are of equal length.

In this case the problem becomes — to prove that twice the sine of the angle of ad- or abduction is equal (or very nearly so) to the difference between the distances from the umbilicus to the internal malleoli.

In Figure I if we suppose D and F, to be the positions of the anterior superior spines of the ilium, A the umbilicus, B and C the internal malleoli, then the angle DRD' (which equals BR'B') will be equal to the angle of deviation (as proven in Figure 2), D' and E' are the positions which the anterior superior spines would have if there was no ad- or abduction.

The Figure D'E'C'B' will be a rectangle. Suppose a circle with a radius BE to be described on B' as a centre; then the points B', C', C and C' will lie in the circumference of this circle, since they are points all equally distant from B'.

It is to be proved that

$$AC - AE = BC' \left(\frac{AC - AE}{2} = \frac{BC' = BE}{2} \right)$$

or if there is an error in the equality, to show that the same is so small as to be inappreciable in the estimation of the ultimate result.

Suppose the triangle A'B'C to be rotated on A'B' as an axis. Then C will fall at C' and the arc B'B' will equal the arc B'C'. On A as a centre with a radius equal to A'B described an arc which shall

* New York Medical Journal, 1884, page 317.

Fig. IV.

cut $A C''$ at S and therefore make $A B$ equal to $A S$. Now $C'' S$ will equal the difference between $A B$ and $A C''$.

From observation in a large number of typical cases the angle of al- or adduction is found not to exceed 30° . It has also been ascertained from observations that the ratio of $A R'$ to $B' R'$ lies within the limits of six to one and eight to one.

It is evident that the smaller the angle of duction and the larger the ratio of $A R'$ to $B' R'$ the less will be the error arising from the assumption that $C'' B$ equals $C'' S$.

Therefore if it is computed, in the case where the angle of duction is greatest equal to 30° and the ratio is smallest equal to 6:1, the value of $C'' B$ and $C'' S$, the quantity by which these two lines differ in length, should be the largest possible error entering into the computation.

Suppose $B' R'$ to be equal to one, $A' R'$ equal to 6 (the smallest ratio), $B' R' B'$ equal to 30° (the largest angle); then $A R' B'$ equals 90° , $B' R' B' = B' R' C''$, $A R' C'' = 120^\circ$ and $A R' B = 60^\circ$.

Since by trigonometry in oblique angle triangle when two sides and the included angle are given the third side is equal to the square root of the sums of the squares on the two given sides diminished by twice the product of these sides into the cosine of the included angle. The formula is

$$C'' A = \sqrt{C'' B^2 + R' A'^2 - 2 \cdot C'' B' \cdot R' A' \cdot \cos. A R' C''} = \sqrt{13} = 6.537$$

$$B A = \sqrt{B' R'^2 + A' R'^2 - 2 \cdot B' R' \cdot A' R' \cos. A R' B} = \sqrt{37} = 5.567$$

$$\text{Therefore } C'' A - B A = .01 \text{ when } B' R' = 1$$

$$\text{But } B T \left(= \frac{B C''}{2} \right) = \sin B' R' T = \frac{1}{2}, \text{ therefore } B C'' = 1$$

Since the greatest pelvic measurement which would have to be dealt with would not exceed 14 inches, and therefore one-half of it not more than 7, therefore the error arising from considering $B T = \frac{C'' S}{2}$ (= sine duction angle) could not exceed .635 of an inch in any case and usually would not exceed .02 of an inch which is a quantity far too small to have any influence in the computing of the table where single degrees only are considered and measurements considered only accurate to the nearest one-eighth inch.

The same relation is easily proved by a similar figure, to exist where the legs are of unequal length. It hardly seems worthwhile to add it here.

Having, then, a right-angled triangle with two known sides, the angle $F L B$ was calculated by the formula, $\sin F L B = \frac{F B}{L B}$, and from the results obtained, the following table was constructed for all breadths of pelvis and all degrees of variation.

The patient lies straight, with the legs parallel. Real shortening is measured with the ordinary tape-

measure, and then apparent shortening is obtained in the same way. The difference between the two shortenings is seen at a glance. The only additional measurement necessary is the distance between the anterior superior spines, which is taken with the tape. Turning now to the table, if the line which represents the amount of difference in inches between the real and apparent shortening is followed until it intersects the line which represents the pelvic breadth, the angle of deformity will be found in degrees where they meet. If the practical shortening is greater than the real shortening, the diseased leg is adducted; if less than the real shortening, it is abducted. Take an example: Length (from anterior superior spine) of right leg, 23; left leg, 22½; length (from umbilicus) of right leg, 25; left leg, 23; difference between real and practical shortening, 1½ inches; pelvic measurement, 7 inches. If we follow the line for 1½ inches until it intersects the line for pelvic breadth of 7 inches, and we find 12° to be the angular deformity, as the practical shortening is greater than the real, it is 12° of adduction of the left leg.

Difference in inches between Real and Apparent Shortening.

Distance between Anterior Superior Spines in inches.

Certain objections which are likely to be made may be formulated and dismissed:

(1) That inequality in the length of the legs, congenital or acquired, would vitiate the result. Any such inequality would appear in both the real and the apparent shortening, and not affect the difference between the two.

(2) That the co-existence of flexion of the thigh upon the pelvis would render the method inaccurate. A moment's consideration will show that the flexion of the thigh upon the pelvis makes no difference, for the measurements here considered depend wholly upon certain relations in a horizontal plane between the iliac spines and the malleoli, and that this relation remains the same, unaffected by the movement of the anterior superior spines in another plane so long as they move together.

(3) It may be urged that individual measurers

vary. But both measurements are taken each time by the same man, skilled or not; and in the measurement for practical shortening he will use the same method, and make the same error that he made in measuring for real shortening, and it will not appear in the difference between the two. It is not unreasonable to expect a moderate amount of care to be taken in any such measurements.

Next and last, as to the practical accuracy of the method: It has been used by the writer and others for some weeks in a large number of cases of hip-joint disease in the Surgical Out-patient Department of the Children's Hospital, and afterward a very careful measurement has been taken independently with a fairly accurate goniometer, and the results have always coincided within one or two degrees.

A FATAL CASE OF PULMONARY BLOOD-EMBOLISM OCCURRING DURING LABOR WITH TWINS.¹

BY CHARLES M. GREEN, M.D.

ON May 31, 1887, I was requested by Dr. O. W. Doe to take charge of a pregnant patient of his during his absence in Europe. The previous history of the patient is irrelevant to this report, except that during her second pregnancy she suffered with varicose veins in both legs. At the time of my taking charge, the patient was supposedly about six months advanced in her third pregnancy: the predicted date of labor was September 6th, and Dr. Doe expected to attend her at that time. Just previous to his departure the Doctor's attention was called by the patient to a swelling of the labia majora accompanied by a painful sense of weight and distention: other than this her health was excellent. It was found that the veins of the vagina and labia majora were much enlarged and engorged, the latter being as large as a man's fist. The lady was kept in bed and a firm compress was adjusted so as to exert an even pressure over the labia. At the end of a week the swelling had greatly subsided and the labia were of nearly normal size: the patient was then allowed to be out of bed, although going over stairs was forbidden for a time, and she continued to wear a supporting compress.

During the month of July the patient continued very well and was accustomed to take an almost daily drive without discomfort and without visible ill-effects on the previously enlarged veins. It seemed to me, however, that she was unduly large for the supposed duration of her pregnancy, and I surmised that there was some error in her dates. On the 4th of August the patient sent for me, thinking that her labor was imminent, although she had had no true pains. Inspection showed the abdomen to be as large as ordinarily at full term, and careful palpation revealed an apparently quite large fetus in O. L. A. position. A second fetus was not then detected, owing, it seemed to me afterwards, to the fact that this fetus was the smaller and was lying in a right posterior position and thereby somewhat masked, by its fellow. The os uteri was found to be the size of a half-dollar, and although there were as yet no perceptible pains, considering the size of the uterus and my previous surmise of error in dates (it being then just a month before

the predicted date), I fully expected the speedy advent of labor. After two days, however, labor had not appeared and the patient was up again, and apparently in her usual health.

I did not see the patient again until summoned to her death-bed, although I was in constant expectation of a summons, and although her husband called one evening in the *interim* to warn me of an expected summons that night. During all my observation of the patient nothing appeared in her condition to excite my apprehension. The varicose veins had so far subsided that I apprehended no danger of rupture during labor, and I expected a normal labor and convalescence.

About quarter-past two on the morning of August 17, the patient awoke and called her nurse: she complained of not feeling well and of difficult breathing; in fact she was soon obliged to sit up in order to breathe comfortably. Uterine contractions probably began before she awoke; and as the pains increased in severity, respiration gradually became more difficult.² I was called ten minutes past four and reached the patient at twenty minutes of five: she was sitting up in bed, with a hurried respiration, and evidently in the second stage of active labor. The face was pale, however, and not flushed as is usual in active second-stage labor: nevertheless, I did not then suspect the real cause of the rapid breathing, but attributed it to the apparent severity and rapidity of the labor-pains. As soon as I could properly disinfect my hands I made a hasty vaginal examination, the patient lying down for the purpose, and found a head already bulging the perineum. I hastily felt the mother's pulse and found it rather weak and rapid; I did not attempt to count it, as one hand was engaged in vaginal examination. In about two pains after my first examination a male infant, found afterwards to weigh 6½ pounds, was born, with occiput right posterior. As soon as I saw the child, I knew that there must be still another in the uterus, as it was too small to have caused so much abdominal enlargement as I had found on previous palpation, and as only the usual amount of liquor amnii had escaped.

But meanwhile the condition of the patient was alarming. Instead of a relief to her respiration by the birth of the child, as I had hoped and expected, the breathing was becoming more hurried: the patient declared that she could not breathe lying down. The pallor increased; the pulse became more rapid, and irregular. I did not auscult the heart, there was no time, but it was evidently laboring. Hypodermic stimulation with brandy and ether was immediately resorted to, and the husband was informed that it was a case of pulmonary embolism and that the issue was probably hopeless: there was obviously no time for procuring a consultation. I persisted in the administration of stimulants with some temporary benefit, until after fifteen or twenty minutes it was evident that all treatment was useless. I then turned and delivered the second fetus as the patient was breathing her last, just forty minutes from the time I entered the house. The patient remained conscious until within two or three minutes of her death.

The second fetus lay in O. L. A. position and was the one felt by me on palpation: it was a girl, weigh-

² The husband subsequently told me that before sending for me he had noticed that the respiration was not natural and had wondered whether I could do anything about it when I came.

¹ Read before the Obstetrical Society of Boston, January 14, 1888.

ing $7\frac{1}{2}$ pounds, and was asphyxiated beyond resuscitation, although prolonged effort was made for that purpose. The first child cried soon after birth and has since thriven. It is quite probable that if I had performed version and extracted the second child immediately after the first one was born, its life would have been saved; but although it was soon evident that the case of the mother was hopeless, I thought it best to continue my efforts in her behalf, and I do not now regret having done so, as this condition is sometimes recovered from.

Although not confirmed by autopsy, the diagnosis of pulmonary embolism of blood-clot seems to be beyond question. Air embolism needs not to be considered, as the embolus evidently became lodged in a pulmonic vessel at about the beginning of labor, before the rupture of the fetal membranes. No antecedent disease of the heart had been suspected or known to exist, whereby vegetations could have formed on the valves and subsequently furnished the fatal embolus.

The source of the embolus will never be determined; but it seems most probable that it proceeded from a thrombus in some one of the pelvic veins. From the known condition of varicosity in the visible veins of the labia majora, it is fair to infer a like condition of at least some of the unseen veins in the pelvis. A sluggish current in some one of these tortuous and dilated vessels must have furnished the thrombus from which the embolus proceeded. It is probable that the embolus was a small one and that it lodged in one of the smaller branches of the pulmonary artery at about the time the patient was awakened by her initial pains of labor and the clinical history suggests a gradual growth of the clot by thrombosis, with extension towards, and perhaps reaching, the heart.

My suspicion of error in the dates, whereby labor was expected earlier than at the predicted time, was, in the light of subsequent events, groundless; as the unusual enlargement of the abdomen was explained by the presence of twins whose combined weight at birth was fourteen pounds. And the threatened labor at the eighth month was obviously the effort of a distended uterus to relieve itself of its contents.

REPORT ON PROGRESS IN THORACIC DISEASE.

BY E. C. SHATTUCK, M.D.

THE LOBAR ARRANGEMENT OF THE LESIONS OF PHthisIS, AND ITS RELATION TO DIAGNOSIS AND PROGNOSIS.

As assistant physician to the Brompton Hospital, Dr. Fowler¹ has had ample opportunity for the clinical study of phthisis in all its stages and phases. In this paper he takes up a point which has, he thinks, not received the attention which it merits—the fact, namely, “that in its onward progress through the lungs, the disease, in the majority of cases, follows a distinct route, from which it is only turned aside by the introduction of some disturbing element”—a previous pleurisy, for instance. The primary focus is very rarely found at the extreme apex, but rather, just above the middle of the clavicle; thence the

lesion tends to extend at first backwards, possibly from inhalation of the virus while the patient is lying down. It is certain that in early cases the signs are not infrequently less equivocal in the supra-spinous fossa than in front. The extension in front in the upper lobe is apt to be on a line about an inch and a half from the inner ends of the first three interspaces.

Infiltration of the lower lobe occurs at a very early period of the disease, and is first to be detected opposite the fifth dorsal spine, midway between the border of the scapula and the spinous processes—somewhat below the apex of the lower lobe. “The infiltration of the lower lobe at this spot in the early stage of phthisis is one of the most constant features in the pathological anatomy of the disease, and its recognition is a matter of much importance, as in doubtful cases it is almost positive proof of tuberculous disease of the lungs.” Extension thence is toward the posterior border of the lung and along the interlobar septum, a line which closely corresponds with the posterior border of the scapula when, with the elbow raised, the hand is placed on the spine of the opposite scapula.

The above-described line of march is not invariable, but is extremely common, especially in cases with slowly progressive disease. The writer thinks that it indicates extension by inhalation of the virus through the bronchi. When the disease spreads by means of the blood or lymph channels the course is more rapid, and extensive miliary deposit is more common.

SARCINA OF THE LUNG.

A long paper by Hauser² can be thus summarized: In connection with all sorts of diseases of the respiratory organs, but especially those associated with cavity formation, the air-passages frequently contain a species of sarcina which is essentially different from that found in the stomach or from any other known species of sarcina. This organism stands in no causative relation to these diseases, nor does it appear to influence their course in any way—in other words, it has no clinical importance.

PULSATING EMPYEMA.

Keppel³ has collected thirty-eight cases, including one of his own. In one or two points his results are at variance with those of Comby, whose paper, based on twenty-seven cases, was noticed in these reports (1884, I, p. 176). To quote from our previous notice: “To sum up, pulsating pleural effusions occur only on the left side, are always purulent, indicate hopeless compression of the lung, and are incurable.” Keppel's own case was serous, followed by recovery, and was right-sided, as was also one other reported case.

THE SURGICAL TREATMENT OF PULMONARY DISEASE.

Runeberg⁴ has collected and analyzed reported cases as far as possible. He laments that, partly from want of detail in the report of the cases, the value of some of his material is impaired.

Of ten cases of pulmonary *abscess* surgically treated, he throws out three as of uncertain diagnosis. Of the other seven cases, in four permanent improvement or complete recovery followed. The other three

³ Deutsch. Archiv, für Klin. Med., 1887, Bd. 41, p. 226.

⁴ Deutsche Archiv, für Klin. Med., 1887, Bd. 41, p. 94.

cases were fatal, but the long delay in operating seems to have been a potent cause of the unfavorable result. A study of these cases would seem to indicate that in pulmonary abscess an operation is desirable, and the earlier it is done the better are the chances for recovery.

Gangrene of the Lung. Out of seventeen cases, in seven there was complete recovery or marked improvement; in two of these, however, the improvement was incomplete, and the final result doubtful; two others required only a superficial operation, like that for empyema. There remain three cases with entire recovery after an operation involving cutting into the lung itself, without which operation it would seem that the termination must have been unfavorable. Of the ten fatal cases, the operation itself does not seem to have materially influenced the result one way or the other, except in two: in one of these there was no adhesion of the pleural surfaces, and the resulting pleurisy certainly hastened death, which would have, however, occurred in any event, as there were several gangrenous foci in both lungs; in the second case the immediate cause of death was apparently a tracheo-bronchitis, excited by irrigation with an irritating fluid.

Echinococcus. Two cases, with recovery.

Bronchiectasis without Gangrene or Clear Tuberculosis. Recovery followed in one case; the other five were fatal. A serious impediment to success in these cases is the fact that the bronchial dilatations are seldom single, and may be unconnected with each other; even if connected, the drainage of all is difficult to secure through an opening into one.

Tubercular Cavities. Six of these have been opened. Death ensued sooner or later in all the cases, though in several there seemed to be temporary improvement.

Since the above was written, we have found another paper on the same subject by Foubert,⁶ who brings out more strongly the good results of operation for hydatid cysts. This writer adds three to the cases collected by Thomas,⁶ making thirty-five in all, with complete recovery in all but five. It is justly remarked that in some of these the cyst, though encroaching on the thoracic space, was really hepatic, and not pulmonary.

If hemorrhage occurs in incising the lung, experience shows that it can be controlled by packing the wound.

THE TREATMENT OF CROUPOUS PNEUMONIA.

Venesection is indicated, according to Fraentzel,⁷ only when, with marked dyspnoea, deep cyanosis, and carbonic acid poisoning, the radials are small and hard — when death is imminent. He is not in favor of the use of digitalis, the good effect of which is lost by reason of the gastric disturbance which characterizes almost every pneumonia of the present day (Berlin), and which, moreover, is apt to intensify the collapse of the crisis. The modern internal antipyretics are specially denounced: there is not the least shadow of proof that the morbid process which underlies the fever is favorably influenced by them in any way, while the harm they do is unquestionable. The time has come when all these useless — nay, dangerous, in that they promote collapse — drugs should be

entirely given up in the treatment of pneumonia. Favorable cases are only interfered with in their progress by the antipyretics; unfavorable cases are hastened to their end. Fraentzel is as uncompromising an opponent of cold baths as of antipyretics: in serious cases cold baths bring the patient, at the very least, to the brink of the grave.

The treatment of which he approves is absolute rest in bed, a nutritious liquid diet, alcohol thrown on the fifth day, though hard drinkers receive the latter and chloral earlier. The delirium of fever and inanition call for morphia, collapse for camphor, etc.

THE DYSPNOEA OF BRONCHITIS.

In the last Report on Progress,⁸ the light which Fraser's experiments with the nitrites throw on the etiology and mechanism of the asthmatic paroxysm was noticed. Professor Fraser⁹ now publishes the results of further experiments with the same class of drugs on bronchitis. He finds that a few minutes after the administration of a nitrite, the dyspnoea, if present, ceases, and the râles disappear. The latter must, therefore, be due chiefly, in this affection, to spasm, and not to secretion, as is generally held and taught.

THE PRESYSTOLIC MURMUR.

About fifteen years ago Dr. Barclay called in question the correctness of the doctrine of the presystolic murmur and its causation, as expounded so clearly and convincingly by Gairdner, who, by the way, prefers the term auricular systolic to presystolic. At that time there was much discussion, which, however, died away entirely, and of late there has been practical unanimity among writers and authorities on cardiac disease as to this point. Recently, the discussion has been revived by an able paper by Dr. Dickinson,¹⁰ who maintains the truth of Barclay's views with as much force and skill as can be brought to bear on the subject.

He urges that the presystolic murmur, "falsely so called," is really systolic and regurgitant, and that its presence indicates a contracted mitral orifice, with valve curtains rigid, but still capable of closure, the murmur being followed by a sharp snap produced by this closure. It will be seen that, according to this view, the clinical significance of this much debated murmur remains practically the same — mitral stenosis. The point of dispute is, rather, the mechanism and time of the murmur.

The arguments advanced by Dickinson are chiefly these: that the presystolic murmur, "falsely so called," frequently is blended with a systolic murmur, there being absolutely no break between them; an impossible condition of things if the murmurs were due to successive currents flowing in opposite directions; some break or pause in the sound there must be under these circumstances; secondly, the difficulty in believing that a force so feeble as that of even an hypertrophied auricle can produce so much vibration; and thirdly, the combined evidence of the senses of hearing, touch, and sight that the sound in question coincides with the period of ventricular contraction.

Dr. Dickinson's paper brings out opposing arguments and opinions from Drs. Gairdner, Graham Steele, George Johnson, Balfour, Sansom, and others.

⁶ Archives Générales, October, 1887, p. 462.

⁷ British Medical Journal, 1885, II, p. 692.

⁸ Fortschritte der Medizin, 1887, p. 446.

⁹ Journal, 1887, p. 278.

¹⁰ Am. Journal Med. Sciences, 1888, p. 122.

¹¹ Lancet, 1887, II, page 620.

The former again speaks of his unique case of ball valve obstruction of the tricuspid, which proves that a loud murmur, precisely similar in character to that generally attributed to mitral stenosis, may be produced by an obstruction to the blood-current from the right auricle to its ventricle.

In short, after carefully reading the arguments adduced on both sides, we can see no reason to cast aside the generally accepted views as to the presystolic murmur; views which, moreover, are supported by cardiographic tracings of Sansom and Galabin.

AN UNDESCRIBED ARTERIAL MURMUR.¹¹

Dr. Seelye, Instructor in Physical Education at Amherst College, finds that in the majority of young men, systolic souffles can be developed over the subclavian and carotids, or about the base of the heart, or even over the whole of one side of the chest, after violent exercise. These sounds are much more frequent in chests more or less nearly approaching the paralytic type, and that heard over the subclavian is often modified by the respiration. The murmurs are not modified by change of position of the body.

The most potent factor in the causation is thought to be some degree of compression of portions of the larger arteries, dilated in consequence of the greater afflux of blood from a heart stimulated by exercise to unusually forcible contraction; of the subclavian against the first rib, of the carotid against the unyielding tendinous portion uniting the two bellies of the omohyoid muscle.

The case is related of a young man who had been warned against over-exertion by his family physician on account of the presence of a cardiac murmur. Dr. Seelye found, on inquiry, that advice had been sought for a pain in the left side, and that the patient had ridden hastily to the office of his physician on a bicycle. Except after active exercise, no murmur was to be heard.

The above observations are important and interesting in these days, when physical culture is absorbing so much of the attention of young men. The great frequency and the lack of clinical importance of subclavian systolic murmurs, heard irrespective of exercise, and often heard only or loudest at the end of inspiration, has long been well known. It has also been remarked that this murmur is especially common in chests wanting in elasticity, and in cases of apex trouble more or less advanced. The further development of the subject by Dr. Seelye is, however, new, and the facts brought out by him should be borne in mind.

FATTY DEGENERATION OF THE HEART FROM INTRA-ABDOMINAL PRESSURE.¹²

A specimen of fatty degeneration of the heart due to intra-abdominal pressure, was shown at the meeting of the London Pathological Society by Dr. Bedford Fenwick. "The abdomen had been swollen for eighteen months; the heart was displaced upwards, and the impulse was diffused. The tumor, which was very large, weighed twenty-two pounds after the fluid had drained away. On the eleventh day after the operation the patient became suddenly worse, and died. The walls of the heart were yellow, soft, and friable. The microscopical appearances were those

of fatty degeneration. He suggested that the cause of the rapid collapse and death sometimes observed in cases of abdominal tumor, both where operation had been performed and had not, was to be found in cardiac degeneration. He had found it present in a considerable proportion of cases of large abdominal tumors. He attributed the degeneration to imperfect oxygenation of the blood, due to the pressure, to displacement of the heart from the same cause, and to the impairment of general health. Fatty degeneration of the liver and other organs had been noted in cases in which large abdominal tumors existed. He had collected twenty-two cases of sudden death in abdominal tumor, in which fatty degeneration of the cardiac muscle was present."

THE TREATMENT OF ANEURISM OF THE THORACIC AORTA BY MOORE'S METHOD.

Charmel¹³ collects twelve cases, and adds three, hitherto unpublished, treated in the clinic of Lépine. The method consists in the introduction through a cannula into the sac of a foreign substance—usually a steel wire or watch spring—about which coagulation of the blood may take place, and obliteration thus brought about.

It is sufficient for our purpose to give the conclusions of the paper, which are as follows:

The procedure was not followed by recovery in any of the fifteen cases thus far reported.

Nevertheless, the operation seems to involve no risk to the patient: post-mortem examination gives some grounds for hope in the future: clinically, this method of treatment has almost always been followed by an improvement in the local condition, as well as in the subjective symptoms of the patient. Therefore, further attempts are not only justified, but should be encouraged.

As regards the details of the operation, it would seem that the best results are likely to be obtained by

- (1) A preliminary exploration of the aneurism by acupuncture needles.

- (2) The introduction of a watch spring through a flat cannula, as advised by Baccelli.

- (3) By the observance of the strictest antiseptic precautions. It is understood that Tufnell's form of treatment should be carried out at the same time.

Clinical Memorandum.

A CASE OF INTUSSUSCEPTION IN A CHILD TWENTY MONTHS OLD; LAPAROTOMY; RECOVERY.

BY WILLIAM N. SWIFT, M.D., OF NEW BEDFORD.

I was called Monday, January 9, 1888, to see a male child, twenty months old. He had never been very strong. About a year ago, had eczema of the chest and neck, but did well with local treatment and cod-liver oil. Last August, had a severe attack of enterocolitis, by which he was very much prostrated. Since that time he had been well until the present illness.

I saw the patient about noon, January 9th. His mother said he had had a cold for a few days. She had given him macaroni for breakfast that was not

¹¹ N. Y. Medical Record, 1887, II, p. 553.

¹² British Medical Journal, 1887, II, p. 1280.

¹³ Revue des Sciences Médicales, 1887, pp. 640 and 809.

very well cooked, and he evidently was suffering from gastric indigestion. I ordered a teaspoonful of the syr. of ipecac, and told the mother to give an enema of warm water if he did not get relief. About two o'clock, after taking two teaspoonfuls of the syr. of ipecac, he vomited, and a short time after the enema was given. About eight ounces of water was injected, and then he was put on a chair, the hole of which was much too large for him, so that his hips went through and he rested on his back. In this position he was urged to strain as much as possible, and had a large, natural defecation. After the defecation he did not seem relieved, and the vomiting continued every two to four hours. The vomiting gradually decreased, and he slept somewhat.

Tuesday (January 10th) morning, he passed some blood, bright red in color, but no fecal matter. He had no vomiting, and began to take nourishment. Temperature normal and pulse very good. He was rather restless and looked badly. He passed blood several times during the day, but this ceased towards night. Passed flatus freely. There was no distension of bowels. During the night he was rather restless, but slept somewhat. There was no vomiting, and he took nourishment well.

In the morning he had several foul-smelling, reddish discharges from the bowels, with some tenesmus. Temperature 98°, pulse 100, rather small and weak. His face was pinched, and the extremities cold. He showed symptoms of shock. Examination by finger in the rectum showed a large, elastic tumor filling the whole rectum, and almost presenting at the anus. The surface of the mass was dark in color, rough, and looked almost gangrenous. I at once made a diagnosis of intussusception, and called Dr. Charles D. Prescott in consultation. He agreed with me in the diagnosis, and we also agreed that laparotomy was the only chance for the child.

At eleven o'clock I operated, Drs. Prescott, George T. Hough, and Garry De N. Hough assisting. I made an incision in the median line about two inches in length, midway between the umbilicus and pubes. Some clear serum escaped from the peritoneal cavity. By inserting the finger I could easily feel the point of invagination, which was in the lower part of the descending colon, about two inches above the sigmoid flexure.

I did not have room enough to get hold of the gut to pull it up, so enlarged my incision downwards as far as possible, and then hooked my finger under the gut and pulled it forward. Dr. Prescott found by rectal examination that the gut was entirely reduced.

Examination of the gut from above showed it to be free, and that the peritoneal coat was in good condition. The wound was closed with silk, and dressed with corrosive sublimate gauze. During the operation careful antiseptic precautions were used. The whole of the operation, including ether and washing, took a little less than an hour.

Before the operation the child showed symptoms of severe shock, but began to improve at once. The bowels moved at four o'clock in the afternoon, and continued regular after that time. There was no vomiting, and Mellin's food, with a gradually increasing amount of milk, was given for nourishment with brandy. The convalescence was complicated with a bronchitis, which, on the seventh and eighth days, was very troublesome; but he improved, and is to-day

perfectly well. The wound healed by first intention.

The points of interest in the case seem to me:

First. The cause, being an injection to move the bowels.

Second. The apparent improvement in symptoms up to a certain point.

Third. The importance of an early laparotomy.

Reports of Societies.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.

F. B. HARRINGTON, M.D., SECRETARY.

FEBRUARY 13, 1888, the President, DR. O. F. WADSWORTH, in the chair.

RECURRENT EMPYEMA IN A CHILD.

DR. ROTCH made the following remarks concerning a case which he considered to be one of recurrent empyema:

Through the courtesy of Dr. J. G. Blake, who operated on the case in January, 1887, and of Dr. A. L. Mason, who had charge of the child when it died in October, I am enabled to report an instance of a condition which, though rarely met with, and pathologically almost an impossibility, seems to clinically deserve the title of recurrent empyema.

A girl three and one half years old was brought to the City Hospital during my term of service, August 2, 1887, by Dr. Fifield, with the following history: She had been breast-fed for a year; she had never had any diseases excepting pertussis when twelve months old, from which she recovered entirely, and was well and strong until November 21, 1886, when she was seized with vomiting and pain in her side and cough; these symptoms continued, and she entered the hospital in Dr. Blake's service January 13, 1887, with a pulse of 140, respirations 48, labored, and temperature 99; the left side of the chest was bulging, respiratory movements were only present on the right side, there was flatness, absent respiratory murmur and diminished vocal fremitus over the whole of the left chest front and back, and the impulse of the heart was in the median line at the tip of the ensiform cartilage.

Dr. Blake aspirated the left chest just below the angle of the scapula, and withdrew twelve ounces of thick pus. On February 4th a permanent opening was made and a tube introduced with antiseptic precautions. The child then rapidly improved, and the tube was removed March 22d. April 15th the physical examination showed scarcely any thoracic depression in the region of the scar or lateral curvature, with good respiration front and back almost to extreme base of lung and normal percussion. She was then discharged well and strong, and is reported to have remained perfectly well until some time in July, 1887, when she began to lose in strength and appetite, to have cough, rapid respiration, and after a time bulging of the left thorax.

August 2d she returned to the hospital, and I found complete flatness, on percussion, both front and back on the left side, with absence of respiration, and heart's pulsations at the right edge of the sternum. Right side of chest normal. Immediately aspirated

the left chest and withdrew twenty-four ounces of inoffensive pus, and as very little improvement followed I made, on August 4th, a permanent opening in the sixth left interspace in the axillary line, and introduced two drainage tubes, the operation being performed with strict antiseptic precautions.

The child then rapidly improved, and by October had a normal temperature, and was up and running about, one tube having been removed October 13th. By November the auscultation and percussion were normal up to within a few inches of the remaining tube, with very little discharge, and the tube was expected to be removed about November 15th.

November 11th was perfectly well, and had a good appetite.

November 12th, 4 A. M., after sleeping quietly, awoke and vomited; did not complain of pain, but looked very pale. The dressing was removed and the tube found to be clear and the lung well expanded, with no thoracic symptoms, the auscultation and percussion being normal, and the wound healed close to the tube, only half an inch of which remained in the chest. The mind was perfectly clear, and the temperature 99. There was on the chest, in front and behind as high as the neck, confined to the area beneath the dressing, an erythematous efflorescence. The dressing was reapplied without iodoform, which had been used before. Nothing was found in the throat.

2 P. M., she was partially unconscious, with mild delirium; and somewhat later had convulsions and a weak rapid pulse, with extreme pallor. The vomiting continued, and by 7 P. M. the temperature was 104. The urine was passed, but could not be obtained for examination. The pupils were equal and reacted. The condition was one of collapse, as from some quickly-acting poison, and from which it was impossible to make her rally.

Death took place at 9 P. M. No autopsy was permitted. Scarlet fever or iodoform poisoning were considered as possible causes of death, but the symptoms were too obscure to admit of any definite conclusion excepting that they did not appear to point especially towards the thoracic organs.

The time which elapsed between the apparently perfect recovery of the child while in the hospital and the second attack of empyema was about three months. In this interval she was described as being fat and blooming, with a good appetite, and with no signs of disease. It should also be noticed that after recovery from the first attack she remained under observation in the hospital for several weeks, and was from time to time carefully examined.

DR. GANNETT, in reply to a question by Dr. Rotch, said that, as far as we can determine by autopsy, recovery from empyema is accompanied by obliteration of the pleural cavity. Sometimes a cake is found with a deposition of lime salts. In the case reported he thought that the recovery must have been more apparent than real, and that there must have been a certain degree of inflammation during apparent recovery. The purulent process may have ceased, and may have been followed by a serous inflammation.

DR. ROTCH said that the physical signs, obtained by several careful observers, seemed to show that no fluid remained in the chest.

DR. HENRY L. BOWDITCH agreed with Dr. Gannett that, possibly, the pleura was not entirely in a healthy

condition between the two attacks. The fact that the child "seemed healthy," and was even "active in the wards," and "apparently well," was not conclusive evidence of health without examination of the thoracic physical signs before the patient left the hospital or subsequently before the second attack.

DR. ROTCH said that as far as could be determined by physical examination the child was well.

DR. GANNETT said that in children the severity of symptoms was a poor guide to determine whether empyema existed or not. He did not depend upon the severity of the symptoms, but preferred to tap the chest.

DR. ROTCH said he found it impossible to make a differential diagnosis in many cases, and that the symptoms often simulate pneumonia. He was in the habit of determining the diagnosis by aspiration with antiseptic precautions.

DR. WHITTIER said he was glad to hear this difficulty of diagnosis spoken of, and that his experience coincided with that of Dr. Rotch's.

DR. ROTCH finally asked Dr. Gannett what he considered the proper nomenclature of this case.

DR. GANNETT replied that he should call the case one of recurrent empyema, however difficult it might be to explain the pathological conditions.

DR. E. N. WHITTIER then read a paper entitled,

THE INFLUENCE OF MALARIA ON THE TYPHOID FEVER OF 1887 IN BOSTON.¹

DR. ABBOTT said that Dr. Whittier's paper was of special interest, inasmuch as it presented one aspect of typhoid fever, which, so far as his knowledge went, had not been seen in Boston before. He had noticed during the past year, in repeated instances, an irregular temperature in cases of typhoid after the second week which were quite inexplicable, but none of them were preceded by chills such as Dr. Whittier had described.

In fact, the cases all occurred before the season at which a malarious element would be likely to show itself: in the early summer. The accuracy of the diagnosis in the cases reported would depend, of course, largely upon the fact of the presence of intermittent fever in Boston. He had not seen or known of the existence of cases of this disease here since its rapid advance towards Eastern New England during the past few years. Some years since he had a case which seemed to have had its origin in Chelsea, where the patient had lived near the marshes of that city. A similar case had been recognized here before, which was attributed to exposure in the same locality. The question to be decided was a very important one, and he felt that the Society was under great obligations to Dr. Whittier for the careful thoroughness with which he had studied and presented all the facts.

DR. F. C. SHATTUCK said that he also had been struck with the rarity these last two years of the typical temperature curve in typhoid fever, and had repeatedly called the attention of his class of students to the fact. Chills, such as those noted in Dr. Whittier's paper, had occurred in a number of his patients the past summer, usually after the typhoid fever had run its course. Some of these chills were evidently connected with phlebitis; in other cases no cause could be detected on very careful physical examination, and the speaker had wondered whether phlebitis was the underlying process in these cases also, seated in a

¹ See page 237 of the Journal.

vein not accessible to direct examination. Some patients had only one of these chills, some several. In no instance was quinine administered, and the chills always subsided, perfect convalescence finally resulting.

The explanation given by the reader for these chills and the aberrations of temperature had not occurred to the speaker.

That malaria has spread eastward in this State, and that it originates in the neighborhood of Boston, perhaps in the city itself, is notorious. The question opened up by Dr. Whittier in his valuable and suggestive paper is one of great interest and of great importance.

Was the blood examined in any of the cases for the plasmodium malariae?

We are fortunate in now having a precise means of diagnosis in doubtful cases of malaria, and it will be the duty of the profession the coming season to carefully follow up the lead given by Dr. Whittier, and settle the question whether malaria is or is not a frequent disturbing element in the local typhoid fever of the present day.

In his service at the Massachusetts General Hospital last summer the speaker had made a special point of the examination of the blood for the plasmodium and had encountered no difficulties except in the attempt to stain and preserve the organism.

In the fresh blood, when one knows what to look for, the bodies are plainly to be seen. But it must be remembered that in the mild forms of malarial fever, such alone as originates in New England, the organisms are to be found in the blood only during the paroxysm.

At least two patients entered the hospital with a distinct history of a tertian ague, were kept in bed, but received no medicine of any kind, and the chills did not recur. This would seem to indicate slight intensity of the malarial poison.

Dr. F. C. SHATTUCK asked Dr. Abbott whether he remembered the occurrence of these unaccountable chills in the typhoid cases coming from the steamer *Prussian*. These patients all came down from a few days to a few weeks after their advent in this country, and they cannot have been much modified by endemic influence during that time and at that season—spring.

Dr. E. N. WHITTIER said that these immigrant cases had been treated by antipyretics, and that for that reason it was difficult to say what would have been the course of the cases without these drugs. Unfortunately no examination had been made for the plasmodium.

Dr. GEORGE B. SHATTUCK thought the greater one's experience with typhoid fever the more was one impressed with the fact that the typical chart—certainly in all stages—was the exception. In some years, it is true, the variations from the type are greater and more constant than in others. The typical chart, however, as a rule, is the exception. Unusual oscillations of temperature, accompanied by chills, occur without as well as with discoverable cause, without the necessity of resorting to malaria as an explanation. When such oscillations are combined with periodicity, the suspicion of malaria is, of course, strengthened, and a history of previous exposure to malarial influences—although long before—lends additional weight. The well-known tendency of ma-

larial taint, even when old, to re-exhibit itself under debilitated or impoverished systemic conditions is, of course, to be taken into account.

Whilst recognizing the fact that malarial influences had distinctly manifested themselves in positive forms within the last year in the immediate neighborhood of Boston, Dr. Shattuck had failed to observe their effects among patients at the City Hospital. At Dr. Whittier's suggestion he had reviewed the course of some peculiar cases of typhoid treated at that hospital the past autumn and this winter, but could not satisfy himself that malaria could fairly be held responsible for the peculiarities of temperature observed. A more careful review might, perhaps, modify this conclusion. He had lately seen a case in consultation in which there were unusual variations of temperature accompanied by chills in the fourth and fifth weeks, after the typhoid process had apparently spent itself, for which the influence of malaria might possibly afford a satisfactory explanation, and he should make additional inquiries as to the patient's surroundings last summer.

Dr. Whittier had made a valuable suggestion, which ought certainly to be carefully followed up next summer and autumn. The malarial wave, which in recent years had passed across Western Connecticut and Massachusetts, up the valleys of the Connecticut and Housatonic rivers, and transferred itself to Southern Rhode Island and Eastern Massachusetts, had shown a tendency to die out as it advanced. The next year or two would, therefore, probably be the best in which to study its influences in our neighborhood.

Dr. B. F. DAVENPORT said that in the early summer he had moved his family out to the region of Watertown. After a short stay one member of the family began to have malaise, with each day a chill at about ten o'clock, A. M., and fever running as high as 103° in the afternoon. He suspected malaria, and his diagnosis was confirmed by Dr. Hosmer. The disease was overcome by the use of quinine. The patient had never been exposed to malarial influences outside of this region.

Dr. GANNETT said that if malaria is going to modify typhoid fever, the modification will at first be slight. In succeeding years it will be more and more marked if it is to modify it at all.

Out-patient physicians must have been struck by the nearness of origin of some of the recent cases of intermittent fever. Two cases of patients, who had never been far from Waltham, were of marked tertian type and were controlled by quinine.

Intermittent fever certainly has its advance and decline. It now seems to be declining along the Hudson.

In the coming years we should study its influence with great care. We must examine for both the typhoid bacillus and the plasmodium malariae.

Dr. ROTCH said that at the City Hospital during his service of four months, very few cases of malarial fever entered his wards and that the charts of his typhoid patients frequently showed great variation from the so-called typical chart. Dr. Rotch also spoke of the danger of giving antifebrine during the period of a disease when a natural fall in the temperature might take place. He had seen two cases in children of most profound collapse from this cause.

Dr. VICKERY said that in 1886, a child who was

born and who had always lived in East Cambridge came to the out-patients department with undoubted intermittent fever.

Dr. J. H. McCollom said that he had seen several cases of intermittent fever, which had originated in the City of Boston. There were marked chills and the disease yielded to quinine. When the Albany Street sewer was being dug a few years ago, he had seen three or four cases of intermittent fever in children who were playing about the street. Some of the laborers also suffered from the same disease.

Dr. Bowditch alluded to a report on intermittent fever in Chelsea, as given by himself with the late Drs. John Ware and Back, at the Suffolk District Medical Society, October, 1852.² Proof was therein given that "certainly three and probably four cases of genuine fever and ague had arisen either on or very near the edge of a partially dried marsh." These cases had occurred during the previous seven years, subsequent to the closure of a dam, whereby the beds of the river and banks adjacent had been exposed, which previously had been covered with tide water. In the appendix to the report is given the case of a boy born and always resident in Boston, between Washington and Tremont Streets. This child had an attack "after sitting on the ground of the Common, witnessing fireworks, a dense fog prevailing at the time."

Also extracts from the Journal of Rev. Noahiah Ruel, 1682-3 he being then a tutor at Harvard College. From this journal we learn that he himself was ill with "ague" 1682, and 1683 that a student died of it.

Dr. Wadsworth in closing, remarked that Dr. Heflinger had told him that the workmen digging a railroad along a high mountainous region in South America had been seized with malignant intermittent fever on first turning the soil, but that afterwards no cases occurred.

(To be continued.)

PROCEEDINGS OF THE OBSTETRICAL SOCIETY OF BOSTON.

C. M. GREEN, M.D., SECRETARY.

TWENTY-SEVENTH ANNUAL MEETING.

JANUARY 14, 1888, the President, Dr. WILLIAM L. RICHARDSON, in the chair.

Dr. Rotch reported a case of

INFANTILE CEREBRAL TUBERCULOSIS,

and compared it with two cases of infantile atrophy, which were under his care at the same time and which so closely resembled in their symptoms and course the tubercular case, that the differential diagnosis was only made clear by the death and autopsy of the latter and the final recovery of the former. The history in all the cases was almost identical, and consisted of breast feeding for a few weeks, followed by different artificial foods and progressive loss of weight, with extreme emaciation, and with nothing to account for this condition excepting mal-nutrition; in fact, it was the negative evidence in all the cases, which made it so difficult to prove that they were not all one and the same disease: this difficulty was still further increased by the atrophic cases, at times showing a decided rise in temperature lasting for days, instead of following

the normal or subnormal rule, usually existing in infantile atrophy. One of the atrophic cases, also, was at one time complicated by an abscess of the scalp, situated over the petrous portion of the temporal bone, which is a favorite locality for abscesses following caries in cases of cerebral tuberculosis: this case also had for a time tremor of the hands and arms.

In other respects all three cases presented the usual uncomplicated symptoms of infantile atrophy and both the atrophic cases had their weight reduced below that which represents the average infant at birth: the atrophic cases then began to gain, and are now healthy strong infants, while the tubercular case after gaining for a time, under the influence of improved methods of feeding, finally began to lose again and died, and it is the absence of symptoms during life, to correspond to the lesions found at the autopsy, which makes this case peculiarly interesting and worthy of record.

CEREBRAL TUBERCULOSIS.

M. M., female: born October 12, 1886, first came under observation October 13, 1887. The history of the early months of life was somewhat indefinite, but no hereditary taint could be ascertained, and the infant was reported to have been fairly well until three months previous to being seen, when it was said to have failed somewhat, and for the last few days to have had a slight cough.

Physical examination revealed nothing abnormal excepting extreme atrophy and a daily loss in weight, which continued until October 25th, when a gradual gain in weight began, continued until November 19th, and was accompanied by a corresponding improvement in the temper and general aspect of the infant. After November 19th the loss in weight began again and continued until December 7th, when death took place.

During the latter period, with the exception of a slight tremor of the hands and arms and an erythematous condition of the left eyelid, the symptoms were negative: the mind remaining clear and the temperature normal until three days before death, when the temperature began to slowly rise, reaching its maximum of 104° on the last day, but not accompanied by unconsciousness or any other change excepting progressive weakness.

[The full report of the autopsy in this case, has by mistake already appeared in the JOURNAL of January 19, 1888, page 76, and will therefore not be repeated here, attention merely being called to the brain, which presented in the lower left cerebellum, and in the left occipital and temporal lobes and right frontal lobes of the cerebrum patches of solitary tubercle as large as a ten-cent piece].

Dr. Rotch drew attention to the latency which characterizes this class of cases, and also to the support which this case gave to the opinion advanced by Hensch that, where the tubercular patches are multiple, there is more likely to be an absence of hemiplegia and unilateral convulsions, and, in fact, of any paralysis or clonus whatever, than where there is one solitary tubercle.

Dr. Rotch also remarked that this lack of symptoms to correspond to the clearly defined lesions found in these cases, renders them much less valuable for the study of cerebral localization than would otherwise naturally be expected and this study made from clinical

² Boston Medical and Surgical Journal, January 26, 1853.

cal deductions drawn from cases of infantile cerebral tuberculosis is rendered still more difficult from the numerous instances which arise where the symptoms, such as hemiplegia and contractions, are found on autopsy to present the corresponding portions of the cortex intact, while various other parts of the cerebrum or cerebellum are found to be the site of the tubercular lesions.

DR. C. P. STRONG reported

SIX CASES OF ALEXANDER'S OPERATION WITH RESULTS.¹

DR. DAVENPORT said that in his opinion this operation has passed the experimental stage, and that now it was a question of results. It seemed to him, as to the reader, that the operation is most applicable to retro-displacements not held by pessaries, and not as a rule to cases of procidentia with loss of perinaeum. In most of the cases he had seen reported, a pessary had been worn for several months after the operation.

DR. BLAKE asked if the operation was applicable to retro-displacements with adhesions.

DR. STRONG replied that if the adhesions were such that the uterus could not be replaced without undue force, the operation was inapplicable; but if they were long and elastic enough to admit of the uterus being raised, the operation was permissible: it was well, however, in such cases for the patient to wear an intra-uterine stem, until the shortened ligament had strongly healed in its new relations.

The reader said that at first he had caused a pessary to be worn in all cases for three months; but he had shortened this period to three weeks, after which time he thought vaginal support was unnecessary, if the patient was careful about undue exertion and lifting.

In reply to a question by Dr. Edward Reynolds, as to whether he allowed the patient to get upon a given day, or whether the time of getting up depended on the weight of the uterus, the reader said he saw no reason why the patient should not get up in two weeks; then, if the uterus were heavy, he would fit a vaginal support that would hold it.

Regarding the size of the round ligaments, Dr. Strong said there was no rule: among his cases, one unmarried woman had fine, large ligaments; another,

¹ See page 166 of the Journal of February 16, 1888.

who had borne many children, had the smallest round ligaments of any.

Dr. CHADWICK had operated in three cases, all of retroversion with complications. In the first case there were tender retro-uterine bands which would not bear the pressure of a pessary: she remained in bed only ten days after operation, wearing a pessary only during that time, and the result was successful. His second case was an undeveloped girl of fifteen, who during the eighteen months of menstrual life had flowed profusely; he had curetted the retroflexed uterus and had tried pessaries; but the latter were not well borne. He then performed Alexander's operation; and although the wound suppurated and was long in healing, the operation was a success. In the third case there were lax adhesions, and although the uterus was replaceable, it was not held in place by pessaries: he therefore operated and the patient was now cured. All three of his patients were virgins. He had no fixed rule about the subsequent use of pessaries; but he believed that when the wound was healed no pessary was usually needed. Of course, if in any case past inflammatory action had caused such adhesions that the round ligament could not be drawn through the ring, the operation would have to be abandoned. As yet he had not removed any of the round ligament, but had left it coiled in the wound: he thought this was useless, however, and hereafter should cut off the superfluous ligament, after having secured it in the ring.

Dr. C. M. GREEN reported

A FATAL CASE OF PULMONARY BLOOD-EMBOLISM OCCURRING DURING LABOR WITH TWINS.²

Dr. LYMAN asked if there had been any dyspnoea during the latter months of pregnancy.

Dr. GREEN said there had been some dyspnoea, especially on walking or other exertion; it was largely for this reason and on account of the weight of the uterine contents that driving had proved to be the most agreeable exercise. The dyspnoea was never excessive, and indeed was no more marked than in most pregnant women with the uterus unusually enlarged by twins, hydramnios, or a large single fetus.

DERMOID CYST.

Dr. JOHN HOMANS showed a beautiful specimen of dermoid cyst³ he had recently removed from a multiparous married woman, aged thirty-six; besides the hair and skin, there were two unsymmetrical bony plates resembling the parietal bones of an infant; these were covered with a membrane like periosteum and had a suture between them exactly like that of the infantile cranial bones. The margins of these bones were studded with teeth of every description,—canine, incisor, and molar. These teeth projected on the concave edge of the bones, and on the concavity or what might be termed the internal surface of these bones, isolated teeth were scattered here and there. A well-marked parietal eminence existed on the bones. It was the finest specimen of dermoid cyst he had ever seen.

SUB-SEROUS FIBROID OF THE UTERUS.

Dr. HOMANS also exhibited a sub-serous uterine fibroid weighing fourteen pounds, which he had removed from an unmarried woman thirty-seven years

of age. He had seen the patient in the spring of 1887, and had advised against operation as her symptoms were not urgent. The tumor had grown, however, and filled both flanks, and not only oppressed the patient by its weight, but also interfered with her work by making it difficult for her to stoop. Moreover, her weight was reduced from two hundred and fifty pounds to one hundred and eighty. He operated without opening the uterine cavity, lifting the tumor out of the abdominal cavity with a corkscrew, thus elongating the pedicle which before compression was about three inches thick. The operation was performed about two weeks previously and the patient had recovered, although the constricting wire had not yet come off from the pedicle. [February 6, 1888, patient up and about.]

In the year 1887 he had performed eight hysterectomies with two deaths. In view of the success claimed for electricity in the hands of Apostoli and others, perhaps the operation of hysterectomy ought to be abandoned; but it should be remembered that Apostoli's method is laborious and tedious, and not certain to cure. For those obliged to live by daily labor, hysterectomy must therefore necessarily be performed in promising cases like the present one, where the uterine tumor grows to such a size as to interfere with the patient's usefulness, and make her life a burden.

Dr. DAVENPORT said that in a recent case of his own he had tightened the wire around the pedicle for three weeks, and as by that time it had failed to come off he had cut away the remaining pedicle.

Dr. CHADWICK said that Apostoli had receded from his original claim that tumors treated by his method would disappear, and now claimed only that the tumors would diminish in size and the symptoms ameliorate. His own experience with Apostoli's method had not been satisfactory.

Dr. ABBOT asked Dr. Homans if it was necessary for the tumor to communicate with the cavity of the uterus in order that there should be hemorrhage.

Dr. HOMANS replied that whether or not there was hemorrhage in any case would depend on the condition of the uterine cavity. In reference to a remark by Dr. Lyman that the majority of patients with fibroids did well without treatment where there was no excessive hemorrhage, Dr. Homans said he had seen two fatal cases of hemorrhage from fibroids during the past year.

"NORMAL FORCEPS."

The PRESIDENT presented a pair of forceps which he had received from Prof. T. Lazarewitch, of St. Petersburg, with the request that they be given to the Society. The instrument has received from the inventor the name of the "Normal Forceps." The blades are parallel to each other instead of crossing at the lock, so that either blade can be easily introduced first. There is no pelvic curve. The lock is formed by a narrow steel plate which passes through an opening in each handle and is held in position by a screw.

— The forty-second annual commencement of the Medical Department of the University of Buffalo took place February 28th, in conjunction with the first annual commencement of the Department of Pharmacy. There were forty-four graduates in medicine, and twelve in pharmacy.

THE BOSTON
Medical and Surgical Journal.

THURSDAY, MARCH 8, 1888.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States and Canada; \$6.00 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 94 Boylston Street.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the "Manager of the Business Department," Medical and Surgical Journal, 94 Boylston Street.

Remittances should be made by money-order, draft, or registered letter, payable to

CUPPLES AND HURD,
94 BOYLSTON STREET, BOSTON, MASS.

TRADE OR PROFESSION?

WE have before us an address delivered before the Maine Dental Society, by Horatio C. Merriam, D., M.D., in which is discussed the question whether dentistry is a specialty of medicine or whether it is a trade. The distinction between trade and profession is presented in a manner which deserves a larger number of readers than is comprised in strictly dental circles.

What would be thought of Dr. Bigelow, the address asks, and how would his name go down in the history of medicine if he had asked or received from his brothers a royalty for each time they had performed his operation for stone, or sold his instruments so that they could be withdrawn from competing with those already in the market? Or even patented and received a revenue on their sale? Would a dealer even venture to approach such a man with a proposition to buy his instruments so as to control their sale? Yet these things are regarded as legitimate and proper in trade but they are condemned in medicine, for the reason that methods honorable in trade may yet be discreditable in a liberal profession. The condition of the general medical profession as shown by such an example differs widely from the position of the dentists, and the author gives various examples of an opposite course of conduct. "A large house has acquired control of all patents on the dental engine, and is thus at liberty to manufacture such only as it may wish, and place its own judgment instead of the profession's." "A dental chair, the invention of a dentist, had been bought and withheld from the profession." "I heard within a few months of a band-piece that a manufacturer had bought for five years, and had thus for five years prevented its coming into competition with those of his own make." "A short time ago I was told of a dentist who took to a manufacturer a form of tooth he had invented. The manufacturer looked at it, then opened a drawer and showed by drawings that he already had the invention in his possession." "Many of our journals are published and

controlled by dealers, and often contain articles in the text advertising materials for sale by their publishers. We often see recommended or offered for sale to the profession articles and medicines, the formulas of which are not given."

"Our dealers have also formed a combination and propose to decide who shall conduct our supply-business, whose gold they shall sell you, whose material they will or will not keep, through what firms you shall order their goods, and they [are] able to take orders for only such goods as the combination choose to offer. They may have the power to interfere with the delivery of an instrument you have ordered if it infringes on a patent held by them."

The author then goes on to say that "they are perfectly right in all that they do or have done if dentistry is a trade and we are tooth carpenters. . . . The brother who sells his invention instead of bringing it before his Society . . . is the one to blame, not the dealer who buys it and shoves it to his advantage. Surgical instrument makers would soon learn to do this if the medical profession would permit." The fact that the onus of such a condition is the fault of the profession and not of the dealers, is enforced by the question, What would be thought of a Cheever or a Hodges or any leading surgeon who would do such a thing as patent and sell his inventions? Yet it would be right if medicine were a trade and they repairers of the clavicle and menders of femurs.

Now these extracts present so forcibly the distinction between a trade and a profession, that they may well be pondered by the Medical Profession at large. If at times it seems a little unfair that one's improvements on surgical apparatus should not directly bring in a fixed income, the opposite condition when everybody should exact royalties and conceal the composition of all new drugs, is too horrible to contemplate—and between perfect freedom on the one hand and patents and copyrights on all new inventions on the other, there can be no middle ground. It is certainly entertaining and instructive to contemplate the unpleasant position which might be, were the general profession to suddenly overturn its present lofty ideal and become a trade.

It would be pleasant to believe the statement as to the position of the dentists an exaggerated one, but as a warning it is perhaps not useless nor entirely needless.

ARE CAUTERIZATIONS OF THE THROAT IN DIPHTHERIA, AND THE FORCIBLE REMOVAL OF FALSE MEMBRANES, TO BE RECOMMENDED?

THERE is no doubt that the prevalent view regarding diphtheria, from the time of Bretonneau to the present day, is that this grave disease, while eminently infectious, is primarily of local origin, not becoming general till after absorption of poison from some limited surface (as the pharynx), which first furnishes lodgment and a breeding place for the mate-

ries morbi or germ. This view has had striking confirmation from the behavior of wounds in the human subject which have accidentally been inoculated with diphtheritic matter, have become the seat of a pseudo-membranous exudation and a focus of infection, and from such experiments on animals as those of Oertel,¹ which go to show "that the disease establishes itself first in one spot, the original focus, and thence radiates, as it were, through the body, until by general blood-poisoning it renders the organism incapable of life."

Such being the theory, there has ever been on the part of practitioners a disposition to attack the disease *in loco*, and arrest it in its incipency; this, in fact, to believers in the primarily local character of diphtheria, really constitutes the leading indication. "Diphtheria," says one of our best writers on this disease, Professor Jacobi, "is analogous to the septicæmia of wounded men and of puerperal women, and the local disinfection which has been accepted as the sheet anchor in the treatment of these affections must be, also, the main reliance in that under consideration."

As to the value of local treatment in this disease, there can hardly be said to be any difference of opinion, and all authorities advise cleansing and disinfectant topical medication. Some, as Billington, Jacobi, and Smith, rely largely on sprays, gargles, and syringing; others, as Liebermeister, make great account of local applications of sulphur.

With regard to energetic cauterizations, and the frequent clearing of the throat of false membranes by swabbing, there has of late years been a general agreement among medical authorities in avoiding these harsher methods, and for the following reasons:

(1) Experience has proved that the violent removal of false membranes does no good, the diphtheritic patches being speedily re-formed. Only when the patches are already loose and ready to separate of themselves, is their removal by the brush or swab really beneficial.

(2) The milder caustics, as nitrate of silver and perchloride of iron, do not penetrate deeply enough to destroy the multiplying infection, and their frequent application adds to the discomfort of the patient.

(3) The stronger caustics (undilute carbolic acid, muriatic acid, caustic potash) are very painful, not easily limited in their action to diseased parts, and are likely to cause dangerous swelling of the tissues.

(4) Add that the patient is often a young child, whose opposition and whose struggles make the difficulties in the management of caustic applications well-nigh insurmountable.

(5) Finally, cauterization of the throat in children has often provoked spasm of the glottis and death from asphyxia; it has also caused lesions of continuity of healthy parts, which have been speedily covered with false membranes.

These considerations, and the results of treatment

by cauterization, which have not been encouraging, have led most authorities to renounce caustic agents altogether.

It is worthy of note in this connection that two French medical authorities, Le Gendre, in the *Archives of Laryngology* (October, 1887), and Gaucher, in the *Annuaire de Thérapeutique* (February, 1888), have endeavored to revive the ancient and now nearly obsolete custom of treating diphtheritic patches by energetic cauterization and the forcible removal of false membranes. Gaucher insists on the doctrine that the angina is "the primary accident of the malady." Diphtheria begins in the throat "because this common vestibule of the respiratory and digestive passages is the most exposed to germs coming from the atmosphere." "The false membrane is the source of the infection of the organism"; hence there is every indication to destroy this membrane *in situ*. To the objection that ablation of the false membrane denudes the mucosa, removes the epithelium, and opens the door to the infection, he replies: "Certainly, if you content yourself with simple ablation of the false membrane. You must, at the same time that you remove the false membrane, cauterize the subjacent mucosa. He employs concentrated phenic acid as the best antiseptic caustic agent. The phenic acid, with just enough alcohol to keep it in solution, is a good form, but Gaucher prefers the following preparation:

R	Acid phenic	10 parts.
	Gaulther	20 "
	Alcohol	10 "
M	Oil of sweet almonds	40 "

This topical agent is, he thinks, less painful than simple carbolic acid; in some cases, however, he prefers the concentrated acid diluted with an equal quantity of oil of sweet almonds. Either of these preparations he regards as an energetic caustic.

A condition of the success of the treatment, according to this writer, is not to be content with "simple touches" or "light brushing," but to endeavor by thorough swabbing or "rubbing" mechanically to detect and remove the false membranes; the underlying mucosa is then left in a deeply cauterized condition, and any further multiplication of germs or spread of the infection is rendered impossible. Gaucher's "swab" is the old-fashioned sponge probang, which is allowed to drip well after being soaked in the acid. Several vigorous "rubs" are given at each sitting, till all the false membranes are removed or destroyed. Then the denuded surfaces are brushed over with the caustic liquid. This operation is repeated morning and evening. Gargles, sprays, and irrigations of carbolic acid (one per cent.), are used freely during the day and night.

The pain which attends these topical applications is severe, but may be mitigated by the cocaine (four per cent.) spray. The inflammatory reaction and the difficulty of deglutition which follow are considerable, but do not, says Gaucher, constitute a serious impediment to carrying out the treatment, which, in his ex-

¹ Ziemssen's Cyclopædia, Vol. I, p. 577.

perience, has been eminently successful. "Out of sixteen cases," he says, "which I have since 1879 treated by this method, I have had as many good recoveries." He admits that this treatment is more applicable to adults than to children, "in whom it is," he adds, "difficult, though not impossible." The two cases which Le Gendre has reported in the *Archives of Laryngology* as treated by this heroic method both got well, as also several cases similarly treated by Albarran.

Practitioners in this country will note with interest the heroic activity of these French physicians, who will probably find few imitators this side of the water.

NATIONALITY AND SCIENCE.

In an address at the opening of the first Scientific and Medical Congress of Holland, B. J. Stokvis considered the inter-connection of national existence and the progress of science. Despite the commonality of methods and rules followed by students of nature (as in music and painting), we do not find uniformity. As Shakespeare is not only the poet, but decidedly an Englishman, so Rembrandt, while a typical painter, is, moreover, a thorough Hollander of Amsterdam in the seventeenth century. Great artists have been and are great because they comprehend the ideas, the feelings of their respective fellow-countrymen, and put into visible, audible form the sentiments which, before, were only vaguely felt in the mento-moral atmosphere. Heroes of science are born amid active life in other portions of the national economy.

Besides the noteworthy fact that the great discoveries in science have been made almost, if not quite, exclusively by the white race, especially by those inhabiting Central and Western Europe and America, it is remarkable that most of the renowned investigators of nature belong to the nations whose citizens have had least restriction, from government or public opinion, placed on personal, political, and social action.

During the eighteenth century, Holland, with Switzerland, was at the head of progress in science. In the course of the first half of the nineteenth she fell back, while the mountain republic still held the van; meanwhile, Germany, France, and England passed forward.

The proverbial neatness and thoroughness of Holland appear in all branches of practical science, especially with regard to technique and nicety in detail of instrument, although her intellectual princes are of the past.

Here arise queries as to conditions and influences that cause the changes in socio-political status, rendering inevitable a stagnation of national mental life, cessation of progress. With the people of Holland, nearly all circumstances of living appear favorable to furnishing means of scientific growth. Why, then, are there among them no prominent active workers in nature's field? But now we come to a region full of hypothesis and arbitrary opinion, and one pertinent

suggestion is ventured. Do they not hold too much to general education, rather than to special development by which discoveries are made? They seem to have enough schools for instruction in science, but few well-furnished laboratories for original work. Students busy themselves in keeping up with the rest of the world, little caring to widen the territory of knowledge. The existence of this Congress is instanced as a proof of the close relationship yet evident between nations and the culture of nature's philosophy, with the hope that from such a concourse of minds may spring incentives to enthusiastic work in regions unexplored.

Whether there be or not any particular dearth of true scientific progress among other peoples, the ideas herein suggested are seed-thoughts well worth development.

MEDICAL NOTES.

— A New York paper states that the whole ship's company of a vessel lying at Philadelphia have been made seriously ill from drinking polluted water. The man who had contracted to fill their tank from the city mains took the water from the river instead, near the outlet of a large sewer. Analysis shows the dangerous character of the water, and the probabilities are that had the ship gone to sea all hands would have perished. Detention by the ice alone prevented it. It would be gratifying to hear of the severe punishment of this contractor.

— In a recent communication of the Academic des Sciences, Bouchard considers naphthol to be the only drug known which has any real effect in the way of intestinal antiseptics while being at the same time in itself not injurious to living tissues. He stated that the toxic dose of naphthol for a man weighing 150 pounds was about 2.50 gm., or half a pound; though toxic but not lethal effects had followed the use of 26 gms. On the other hand a daily dosage of 2.50 gm., or 40 grains will secure intestinal antiseptics. The relative anti-septic power and toxicity of various drugs are thus tabulated by this observer.

	Antiseptic dose.	Toxic dose.	Daily toxic dose.
	Per 1000.	Grammes.	Grammes.
Iodoform.....	1.27	0.50	0.05
Iodol.....	2.75	2.17	1.24
Naphthol.....	1.51	3.40	1.00
Beta-naphthol.....	0.40	3.80	1.10

— Dr. Crozer Griffith reports in the *Therapeutic Gazette* encouraging success from the treatment of whooping cough by antipyrine. The drug was used in doses of from gr. iss to iii for children from one to five years, and was repeated from three times a day up to every two hours. In many of the cases, at the acme of the disease, immediate improvement was noted to follow the use of the drug.

— The following somewhat unusual action of a medical man in reference to secrets of the medical "confessional" is narrated in the *India Medical Gazette*. In the court of Madras, A prosecuted B under the Penal Code, for adultery with A's wife. The fact was sworn to by A's wife in court. Dr. C., a surgeon

in the Madras medical service, sent word to the counsel for the defence that he could give testimony which would help the accused. On being summoned, he narrated facts made known to him in conversation with Mrs. A., regarding a previous adultery. This evidence was ruled out as Mrs. A. was present to declare what she did say, and she totally repudiated the conversation. The judge, moreover, censured the doctor for volunteering to give away the secrets reposed in him professionally, but said that if he were summoned involuntarily he would have been obliged to testify to facts thus learned. If the latter is the case, and the law had no respect for professional secrecy when it summons a witness to its own aid, it is a delicate question how far, supposing the doctor to have been honest in his testimony, he was obliged to sit still and see an innocent man suffer injustice from want of that evidence which under slightly different circumstances, the law has a right to extort.

BOSTON.

—The fortieth annual report of the Massachusetts School for the Feeble-minded at South Boston has been presented to the State Legislature. During the past year the school has for the first time been in condition, through the liberality of the State appropriation, to obtain the services of a *resident* superintendent, which the trustees rightly consider a great step gained. An appropriation of \$20,000 was also made to purchase a new site for the school, and two estates in Waltham, containing a little over seventy-two acres, have been secured for the sum of \$12,859. The remainder of the appropriation is to be used when it seems desirable, to secure additional land. The property now occupied by the school at South Boston and at Medfield is proposed to be given up whenever the new site is ready for occupancy, and the sale of the former will in part pay for the new buildings, though a liberal additional appropriation for this purpose is asked for. The average number of pupils present during the last year was one hundred and seventy-nine. Of twenty-seven discharged, eleven died, five of them by tuberculosis. The expenses for the year were \$14,500.

NEW YORK.

—The tablet erected by the Alumni Association of Bellevue Hospital Medical College in memory of the late Austin Flint, M.D., at the Carnegie Laboratory, will be unveiled on Saturday evening, March 10th, at half-past eight o'clock.

—The American Veterinary College held its thirtieth annual commencement at Chickering Hall, March 1st, when there were thirty-two graduates. Prof. F. D. Weiss, President of the Board of Trustees, presented the diplomas, Prof. Charles A. Doremus awarded the prizes, and Prof. F. S. Dennis, of Bellevue Hospital Medical College, delivered the address to the class.

—At its meeting of March 1st, the Academy of Medicine passed a resolution endorsing the petition of

the Georgia State Medical Society to Congress to place medicines, medical and surgical apparatus, and anything used in the diagnosis and treatment of disease, on the free list.

—Typhoid fever recently broke out among the students at St. Stephen's Episcopal College at Annandale on the Hudson, caused, it is said, by impure water obtained from a well near the College chapel; and in consequence of the panicky feeling prevailing, most of the students have gone to their homes.

—Dr. Joseph B. Holder was attacked by apoplexy February 26th, and died on the 28th. He was born at Lynn, Mass., in 1824, and graduated from the Medical Department of Harvard University. Always an ardent student of natural history, through the influence of Professors Agassiz and Baird, he was sent in 1859 to Dry Tortugas as a naturalist, and he then began his first researches in invertebrate zoology; among the results of his studies along the Florida coast being several papers contributed to *Harper's Monthly*. During the late war he was an army surgeon, and in 1870 came to reside in New York, where, up to the time of his death, he occupied with distinguished credit to himself and the institution the position of Curator of Invertebrate Zoology in the American Museum of Natural History. He was a member of the New York Academy of Sciences, the Society of American Naturalists, the Harvard Club, and the Linnean Society of New York. Besides having revised and adapted Wood's "Natural History of the World," he was the author of "Fauna Americana," and a frequent contributor to the *Century*, the *Scientific American*, and other periodicals. Dr. Holder leaves a widow and one son. From early youth he was a member of the Society of Friends, and he was buried in the family burying ground at Lynn.

—The new Loomis Laboratory of the Medical Department of the University of the City of New York was open for public inspection on Monday evening, February 27th.

—An experiment is shortly to be made to show to what extent the dairy resources of Central and Western New York, which have hitherto been regarded as too remote to furnish supplies, can be made available in meeting the growing demands of the city for an increased milk-supply. It is believed that by the judicious adaptation of the refrigerative process milk produced in any part of the State can be landed in New York, even during the heat of the summer season, in a perfectly sweet and wholesome condition. Accordingly, refrigerator receiving houses are now being built at a number of the railroad stations in Broome and Cortland Counties, at distances varying from 210 to 250 miles from the city where the producers will deliver their milk, and where it will be cooled down to a temperature of 30°. It will thence be transported to town by the Delaware, Lackawanna and Western Railroad, which has had a number of improved refrigerator cars constructed for the purpose.

Miscellany.

TRICHINOSIS IN GERMANY.

THE United States minister at Berlin, in his dispatch under date of January 30th, transmits copies and translations of two articles taken from Berlin newspapers containing reports, which have not been contradicted, of further alarming outbreaks of trichinosis in that country. The articles referred to are as follows, and are published in the Sanitary Report of the Marine Hospital Service for the week ended February 24, 1888:

Görlitz, January 23d.—Trichinosis has continued to spread in the Saxon boundary region. The attacks of the disease are no longer confined to Ober-Cunewalde, but have also occurred in Oppach, Laivalde, Beiersdorf, Lauba, Halbau, etc. The number of persons attacked is already over one hundred. Three cases have as yet resulted fatally. As regards the origin of the disease, it is said that a butcher of Ober-Cunewalde on Christmas eve made to his customers a present of smoked sausages, in the preparation of which meat containing trichina had been used. In all the families which had received and eaten those sausages, attacks of the disease occurred.

From Saxony, January 26th (own correspondence). In view of the visitation of epidemics of the trichinosis with which several places in Saxony have of late been afflicted, the local authorities (Amtshauptmannschaft) at Plauen i. V. have recently issued a decree urgently recommending to the individual communities of the district the introduction of obligatory examination for trichinosis. In Ober-Cunewalde the persons attacked by the disease have attained to the number of about one hundred and seventy, and nine deaths have hitherto occurred. At the village of Obersachsenfeld, near Schauenberg, a new epidemic of trichinosis has broken out, resulting as yet in the occurrence of twenty cases of the disease. At Ober-Cunewalde a committee has been formed to aid the poor among the persons attacked.

THE TREATMENT OF CARBUNCLE BY CARBOLIZED SPRAY.

A LECTURE on the above subject by Professor Verneuil, of Paris, is translated for a recent number of the *Medical and Surgical Reporter*, in which the distinguished surgeon takes very conservative ground in the matter of the surgical treatment of furuncle and carbuncles. Beginning with the treatment of long free incisions, he gradually restricted operation to grave and well-marked cases, and of late treats all carbuncles, small or large, diabetic or not, painful or painless by simple carbolic spray (two per cent.), applied by steam atomizer for an hour at a time, three or four to a day. He has found this proceeding to remove pain and offensive odor, as well as to reduce swelling even in diabetic subjects, and to be freer from resulting septic infection of the general economy than the more common use of the knife. It is not claimed that this treatment will prevent accidents which may occur when the carbuncle has given rise to an extensive sphacelus in extremely cachectic patients. But in the majority of cases, if taken early

he believes that we have in the spray an abortive treatment for carbuncle.

The lecture is thus summed up, in closing: (1) Furuncle and carbuncle are only different stages of one infectious disease, and are to be treated by the same therapeutical means. (2) The treatment consists in surgical interference or medical applications. The first was formerly thought to be indispensable, or at least was resorted to in the majority of cases. The second were thought to be efficacious only in mild cases, and were employed as secondary measures for relief. (3) To-day surgical intervention is becoming less and less necessary, and should be reserved for exceptional cases; on the other hand, antiseptic solutions of carbolic and boric acid, etc., used in a peculiar way, and especially under the form of prolonged and repeated atomization, are remarkably efficacious, while they are at the same time very simple and free from danger. (4) Sprays, with very few exceptions, lead to a rapid recovery from the manifestations of furuncle or of a small carbuncle, and they check the disease in graver cases. They very rapidly put an end to the pain, the fever and the general symptoms; they disinfect the purulent and gangrenous spots, and assist the cleaning of the lesion and the formation of granulation tissue. (5) Sprays may be used in any region of the body for all forms, and in all the stages of the disease. They are never dangerous, and will alone bring on a cure in the majority of cases. They would also help greatly to the success of surgical interference, if such should be deemed necessary. (6) Finally, they prevent internal auto-inoculations and the phenomena of general infection.

Correspondence.

CERTAIN ADVANTAGES OF CAÑON CITY, COLO., AS A RESORT FOR CONSUMPTIVES.

MR. EDITOR.—While a considerable number of careful reports and deductions have been made of late by competent observers concerning the value of Colorado climate for invalids, the extent of country in consideration is so large that comparative meteorological reports of its various localities are especially needed by climatologists and physicians. Denver, as the rapidly growing metropolis within this great western health belt, and Colorado Springs as its most popular resort, have received a large share of attention. It is well, then, in this connection, to consider other Colorado points which may exhibit variations of climatic advantage to the health seeker. For this reason a simple statement of meteorological conditions at Cañon City is herein made without unnecessary embellishments.

Situated south of the State "divide," in the valley of the Arkansas, immediately as it broadens from its narrow defile through the mountains, the town stands at an elevation of 5,287 feet. Open to the plain, it is flanked and backed by mountains, which not only offer a panorama of surpassing picturesqueness, but also necessarily furnish a shelter from the intensity of the prevailing west winds—one of the few objectionable features of Colorado climate to some invalids. But it is to the temperature as a distinctive local feature that attention is especially called, and the importance of this feature to the invalid who depends for improvement on his facilities for an out-of-door life, warrants careful consideration. It is in this particular that the following figures, taken from reports made for the Signal Service for the month of January, 1888, will be of significance:

	Elevation.	Temp.
Denver	5,200	27.3
Colorado Springs	6,000	26.9
Pueblo	4,500	27.9
Santa Fe, N. M.	7,000	30.9
Canon City, Col.	5,500	32.4

These figures, while below the average mean for January — unusually cold weather having prevailed throughout the West — yet exhibit an important variation in favor of Canon City. To attempt to account for this variation would lead further into the realm of theory than will be necessary to go, but the sheltered position of the town, and the presence of extensive limestone cliffs, which retain their heat, offer a ready explanation. This retention of heat will also explain the lesser mean daily range of temperature which prevails here — another notable variation from the points compared.

The climates of Minnesota on the one hand, and Florida and Southern California on the other, are both recommended for phthisical patients, yet the depressing cold of the former, and the enervating warmth of the latter, are extremes to which the above figures show that Canon City would form an agreeable mean.

It may be said, however, that a consideration of temperature alone should not be urged unless conjoined with that of other climatic conditions favorable to the pulmonary invalid. Of these dryness, altitude and sunshine are generally conceded to stand foremost. The atmospheric dryness of Colorado is now too well known to need mention, and in this Canon shares in common with its neighboring points. Less than two inches in depth of light snow fell during January, and not a drop of rain. Dr. Fisk, of Denver, in a recent admirable article in the *Boston Medical and Surgical Journal* calls attention to the fact that in no other region in the world accessible to invalids is there a greater proportion of sunny days than in Colorado. In this respect Canon fairly excels the record with but one cloudy day during January, with twenty-five clear and five fair. The influence of this almost unusual daily reign of sunshine, with a dry earth underneath, to facilitate an out-of-door life will be at once apparent.

The most favorable meteorological conditions, however, do not supply all the wants of the invalid. An important inquiry concerns his shelter, food, and opportunities for recreation and social enjoyment. For these Canon furnishes three first-class hotels, long accustomed to supply the wants of invalids, at a cost very considerably less than the hotels of Denver and Colorado Springs. While at the latter place good board is quoted at \$12 to \$15 per week, the same accommodations can be had in Canon at \$9 to \$12. For permanency of location — and this is always to be urged — cottages can be rented at equally reasonable rates. The town, settled among the earliest in the State, contains a population of 3,000 people, as peaceable, prosperous, and free from the rougher element as the best of eastern towns. The substantial and comely aspect of its public buildings and private residences attest to its respectability, while its tall shade trees, wide lawns and extensive orchards give it grace and beauty. To this last feature it is well to give especial emphasis, as it opens a field for healthful and lucrative industry to the permanent settler, Canon being one of the chief fruit-growing points in the State, with a large irrigated area of land open for cultivation.

For attractions of natural objects the health seeker can find no better practicable resort in America than here. Those unaccustomed to an environment of lofty mountains can form but little conception of the constant diversion their ever-changing aspect excites in the mind of the beholder. Under this influence the invalid is stimulated to an exhilarating exercise of his powers, which a monotony of landscape and an enervating atmosphere stagnates. This drives, rides, or walks into the canyons, or over the wide stretches of tableland are daily sources of enjoyment and profit. Horse-back riding is very generally practiced from the little expense involved, good riding ponies in many cases being procured for the winter season for their mere board. A daily beneficial custom with many is a visit to the soda and iron springs here, which are equal to any in

the State for pleasant medicinal properties. A hot spring, with the best of bathing facilities also exists here.

In the above exposition of facts the writer has aimed at detailing certain advantages that Canon City, while sharing in the general features of its neighboring health resorts, possesses over them. These advantages may be summed up to be a comparatively mild winter temperature without loss of invigoration, a comparative immunity from high winds, and a minimum in the expense of living with a maximum of healthful attractions. These features, taken into conjunction with the general atmospheric dryness of this region, with an altitude highly stimulating in its effects but not excessive, with as large a proportion of sunny days as is to be found anywhere in this sunniest of all climes — facts to which records in this journal have already borne witness, — furnish strong claims for attention. These facts, then, are presented to physicians for consideration in recommending certain climates for their consumptive patients, and while it is not the purpose of the writer to enter into a discussion of the fitness of the course to be pursued in different classes of cases, from an experience of two seasons in different health resorts, of the Southern States, and from present observation in Colorado, he is impelled to say that in the general run of cases not advanced to the last stage of the disease, the invigoration imparted to mind and body is in such apparent large proportion, and the disappearance of active symptoms is so much more general in the latter locality that could an opportunity for its observation be given to the advising physician, there would no longer be any hesitation regarding the choice for his patient.

Yours very truly, WM. T. LORD, M.D., (Harv.)

LETTER FROM ST. AUGUSTINE, FLORIDA.

ST. AUGUSTINE, FLA., February 25, 1888.

MR. EDITOR, — The wonderful changes wrought by private enterprise in this ancient burg during the past year have not at all affected the old portion of the city, which is as sleepy, picturesque and indescribably odd as ever. The fire of last spring destroyed a number of ram-shackle buildings, mostly built of wood, and would have proved a veritable blessing if it had spared the old cathedral — the walls of which alone remained. It is now in process of restoration; a transept is being added, and we must hope that it will look "as good as old." Among the buildings burned were one or two which will be missed — particularly "Doctor" Vedder's museum, which together with some fine specimens of the *crotales horridus*, was completely destroyed. The old gentleman has found a new location for his treasures near the yacht club, and seems to be enjoying a fresh era of prosperity. The greater portion of his collection was saved, including the fine old snake who always shows his resentment of the near approach of strangers by sounding his rattles — thereby offering a capital opportunity to one wishing to learn to distinguish the difference between their distinctly intermittent vibration and the continuous hum of the locust. The crane whose loss of a leg has been artfully supplemented by a wooden contrivance (thereby giving him while in motion the appearance of being in his cups) was also rescued, together with the pet pelican, and are to be seen in the flesh on payment of the usual price of admission.

Next door to Vedder's stands a house on the site of one destroyed by the fire, which is an exact reproduction of its predecessor; it is even said that its door-bell just as the former one did, declines to ring, a fine example of unconscious celebration on the part of the bell-ringer.

The plaza looks the same as ever, except that the roof of the old "slave-market" and some of the large trees at the eastern end have gone. On the benches, basking in the sun, are to be seen "crackers," minorcans, and the ever-present colored brother, sitting in amicable propinquity; while tied to the rail fence is the usual collection of saddle horses and mules.

¹ Vide recent articles by Drs. Fisk and Otis on Colorado climate.

One sleepy-looking roan I distinctly remembered having seen standing in the same spot a year ago, and it pleases my fancy to believe that he has remained there quietly ever since, while his rider is taking a prolonged nap in some shady nook. St. George Street is certainly rather muddier than last year. In the shop windows are to be seen the usual display of young alligators, turtles, fruit and curios of all sorts. No greater contrast can be imagined than that between the old town and the magnificent new portion now rapidly springing up. The stately Ponce de Leon, superb in every detail, and the solid and picturesque Casa Monica and Alcazar all front upon the Alameda (as King Street is now called) and together with a morish villa occupied as a private residence, form a group well worth a special pilgrimage. All these buildings

drain to the harbor, and thus far I have seen nothing in the way of sickness which can be attributed to any defects in their sanitary arrangements. The class of invalids who come here has radically changed during the past decade. Consumptives go to Thomasville, Aiken, or some of the other resorts situated in higher altitudes, while people with irritable throats, rheumatism, and chronic bronchitis seem to prefer Florida. Travel has been enormous this year, and during the President's stay, decent quarters were in some instances absolutely unobtainable. I have had an opportunity of trying the effects of permanganate of potassium (subcutaneously injected) upon a dog, bitten by a rattlesnake, and hope to be able to do something further in this line of experiment before my return.

Yours very truly, AN ITINERANT M.D.

REPORTED MORTALITY FOR THE WEEK ENDING FEBRUARY 25, 1888.

Deaths reported 2,640; under five years of age 921; principal infectious diseases (small-pox, measles, diphtheria and croup, diarrhoeal diseases, whooping-cough, erysipelas and fevers) 355; acute lung diseases 477; consumption 387; diphtheria and croup 131; scarlet fever 62; typhoid fever 34; whooping-cough 28; diarrhoeal diseases 28; measles 23; malarial fever 18; cerebro-spinal meningitis 17; erysipelas 12; perneal fever eight; small-pox one, typhus fever one. From whooping-cough, Baltimore eight, New York and Boston four each, Brooklyn three, Philadelphia, Portland, District of Columbia, Pittsburgh, Milwaukee, Charleston, Lowell, Lawrence and Salem one each. From diarrhoeal diseases, New York 13, Philadelphia, Milwaukee and Holyoke three each, Boston two, Baltimore, Pittsburgh, Charleston and Lynn one each. From measles, Baltimore nine, District of Columbia eight, New York four, Pittsburgh and Milwaukee one each. From malarial fever New York nine, New Orleans five, Philadelphia two, Brooklyn and Baltimore one each. From cerebro-spinal meningitis, New York five, Fall River three, Philadelphia, Milwaukee, Nashville and Worcester two each, Lynn one. From erysipelas, Baltimore eight, New York and Boston four each, Brooklyn three, Portland, District of Columbia, Pittsburgh, Milwaukee, Charleston, Lowell, Lawrence and

Salem one each. From perneal fever, New York and Philadelphia two each, Brooklyn, Pittsburgh, District of Columbia and Milwaukee one each. From small-pox, New York one. From typhus fever, Philadelphia one.

In 22 cities and greater towns of Massachusetts with an estimated population of 1,047,250, the total death-rate for the week was 24.03 against 23.20 and 22.90 for the previous two weeks.

In the 28 greater towns of England and Wales with an estimated population of 3,398,275, for the week ending February 11th, the death-rate was 22.2. Deaths reported 3,985; infants under one year of age 896; acute diseases of the respiratory organs (London) 504; whooping-cough 212; scarlet fever 74; diphtheria 65; measles 40; fevers 38; diarrhoea 36; small-pox (Sheffield 31, Bristol, Nottingham and Leeds one each) 36.

The death-rates ranged from 15.2 in Brighton to 36.4 in Preston; Birmingham 20.0; Bradford 19.3; Derby 16.8; Hull 17.8; Leeds 19.2; Leicester 19.9; Liverpool 22.8; London, 22.4; Manchester 28.2; Newcastle-on-Tyne 24.0; Nottingham 22.6; Oldham 24.2; Sheffield 24.3; Sunderland 28.1.

In Edinburgh 22.2; Glasgow 24.1; Dublin 29.9.

The meteorological record for the week ending February 25, in Boston, was as follows, according to observations furnished by Sergeant O. B. Cole, of the United States Signal Corps:—

Week ending	Barom-eter.	Thermometer.		Relative Humidity.			Direction of Wind.		Velocity of Wind.			State of Weather. ¹			Rainfall.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM FEBRUARY 25, 1888, TO MARCH 2, 1888.

SHILLOCK, PAUL, to be assistant surgeon, with the rank of first lieutenant, January 31, 1888.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE UNITED STATES NAVY DURING THE WEEK ENDING MARCH 3, 1888.

HEYL, T. C., surgeon. Ordered to the receiving ship "St. Louis" revoked.

WHITE, C. H., surgeon. Present duty continued to October 1, 1888.

STREETS, T. H., surgeon. Ordered to the receiving-ship "St. Louis."

DRENNAN, M. C., surgeon. Ordered to the receiving-ship "Vermont."

BURSH, G. R., surgeon. Detached from the receiving-ship "Vermont" and to the "Pensacola."

MEANS, V. C. B., passed assistant surgeon. Detached from Naval Hospital, New York, and to the "Pensacola."

HOEHLING, A. A., medical inspector. Detached from the "Pensacola" and wait orders.

HARMON, G. E. H., passed assistant surgeon. Detached from the "Pensacola" and wait orders.

EDGAR, J. M., passed assistant surgeon. Detached from the "Pensacola" and wait orders.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE UNITED STATES MARINE-HOSPITAL SERVICE, FOR THE WEEK ENDING MARCH 3, 1888.

STONER, G. W., surgeon. Detailed as chairman of board for physical examination of officers and candidates, Revenue Marine Service. February 28, 1888.

URGUYMET, F. M., passed assistant surgeon. Detailed as recorder of board for physical examination of officers and candidates, Revenue Marine Service. February 28, 1888.

KALLOCH, P. C., passed assistant surgeon. Relieved from duty at Pittsburgh, Pa., ordered to Marine Hospital, San Francisco, Cal. March 2, 1888.

CARRINGTON, P. M., passed assistant surgeon. Relieved from duty at Marine Hospital, San Francisco, Cal., ordered to assume charge of service at Pittsburgh, Pa. March 2, 1888.

KINYOON, J. J., assistant surgeon. Granted leave of absence for twenty days. February 28, 1888.

SOCIETY NOTICES.

MASSACHUSETTS MEDICAL SOCIETY, SUFFOLK DISTRICT.—THE SECTION FOR CLINICAL MEDICINE, PATHOLOGY AND HYGIENE will meet at 19 Boylston Place, on Wednesday, March 14th, at 7.45 o'clock. Papers: Dr. John A. Jeffries, "On the Sterilization of Milk for Infants." Drs. H. C. Haven, and T. M. Rutch will open the discussion. Dr. Albert N. Blodgett, "The Diagnostic Value of Hemoptysis in Pulmonary Disease." A. L. Masos, M.D., *Chairman*.

ALBERT N. BLODGETT, M.D., *Secretary*.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.—A Regular meeting of the Society will be held Monday, March 12, 1888, at the Medical Library, 19 Boylston Place, at quarter of eight, P.M. Reader: Dr. A. M. Hodges, subject, "Constipation and some of its Accompaniments." Dr. A. T. Cabot will show "A Large Urethral Calculus Removed by Operation." Dr. H. H. A. Beach will show a "Cancerous Tongue Removed by a Bloodless Operation." Drs. C. B. Porter, E. H. Bradford and John Romans will exhibit specimens.

F. B. HARRINGTON, *Secretary*.

APPOINTMENTS.

Dr. Edward B. Lane, formerly first assistant at the Boston Lunatic Hospital, has been appointed first assistant at the Northampton Lunatic Hospital.

Dr. Robert Swift has been appointed first assistant, and Dr. Charles G. Dewey second assistant, at the Boston Lunatic Hospital.

The following recent appointments have been made upon the staff of the Massachusetts Charitable Eye and Ear Infirmary: Ophthalmic Surgeon, Henry W. Bradford, M.D.; Aural Surgeon, E. D. Spear, M.D.; Assistant Ophthalmic Surgeon, Myles Standish, M.D.; Assistant Aural Surgeons, F. L. Jack, M.D., and H. L. Morse, M.D.

LECTURE.

A paper entitled "The Transportation of the Wounded," will be read by Assistant Surgeon James E. Filcher, U. S. A., before the Military Service Institution, at Governor's Island, New York Harbor, on Tuesday, March 13, 1888, at 2 P.M. Leave Barge Office, Battery, 1.30 P.M.

J. F. RODENBORGH, *Secretary*.

BOOKS AND PAMPHLETS RECEIVED.

Insistent and Fixed Ideas. By Edward Cowles, M.D., Professor of Mental Diseases, Dartmouth Medical College; Medical Superintendent, McLean Asylum, Somerville, Mass. Reprint. 1888.

A Second Clinical Study of Hemianopsia. Cases of Chiasm-Lesion. Demonstration of Hemioptic Pupillary Inaction. By E. C. Seguin, M.D., Corresponding Member of the Société de Biologie de Paris, of the Verein für innere Medizin of Berlin, Honorary Member of the Société Anatomique of Paris, etc. Reprint. 1887.

Fortieth Annual Report of the Trustees of the Massachusetts School for the Feeble-Minded at South Boston. For the year ending September 30, 1887.

A Treatise on Sabel, the New Remedy for Rheumatism and Rheumatic Affections. Diarrhea, Dysentery, Typhoid Fever, etc., and Antiseptically as a Surgical Dressing. Second Edition. New York: W. H. Schieffelin & Co. 1888.

Two Laparotomies on Same Patient.—Removal of Both Ovaries for Cystic Disease, and also a Large Tumor of the Mesentery.—Silk Ligature Passes into the Bladder and serves as the Nucleus of a Calculus. By R. A. Kinloch, M.D., of Charleston, S. C.

Passive Motion in the Treatment of Paralysis of the Ocular Muscles. By Charles Stedman Bull, M.D., New York, N. Y. Reprint. 1887.

ADENOID VEGETATIONS IN CHILDREN: THEIR DIAGNOSIS AND TREATMENT.¹

BY FRANKLIN H. HOOPER, M.D.

In a paper² read in February, 1886, before the Boston Society for Medical Improvement, I endeavored to give the history, symptoms, and treatment of a disease incident to childhood which has its seat in the naso-pharyngeal cavity, and to which Wilhelm Meyer, of Copenhagen, in 1868, gave the name of *adenoid vegetations*.

Our knowledge of this affection has been acquired during the few years which have elapsed since the appearance of Meyer's³ and Loewenberg's⁴ important communications; but any one who has had practical experience with it, and has witnessed the surprising improvement in certain children after its eradication, cannot fail to wonder why it should have remained so long unrecognized and untreated. It remained untreated chiefly because it was unrecognized. The naso-pharyngeal cavity of the child has always been, and is, even at the present time, a much neglected region. It is the rare exception that a posterior rhinoscopic examination can be made in little children on account of the irritability of the fauces, especially if any catarrhal trouble be present; nor can the cavity be inspected through the nostrils. Hidden from sight, this important region has been left practically unexplored. Nevertheless, the cause of obstructed nasal respiration in children, in the majority of instances, will be found to be in the naso-pharyngeal cavity, and not in front of it, in the nasal chambers, nor below it, in the pharynx. Yet how few practitioners are in the habit of interrogating this cavity, and how many students leave their medical schools and hospitals without once having passed their index-finger up behind the soft palate, and learned to recognize by digital examination the different anatomical landmarks there contained, or how to know by the sense of touch when its walls are in a healthy condition, and when they are the seat of disease. The naso-pharyngeal cavity is seldom looked into in the dissecting room or on the autopsy table, and receives, as a rule, most inadequate mention in works on general medicine and surgery. Children presenting symptoms peculiar to adenoid growths in this region are frequently discharged with the not very definite diagnosis of "catarrh," "snuffles," "winter cough," "winter cold," etc., whereas, if their naso-pharyngeal cavities were properly examined, the true source of their discomforts would be discovered. Such little children, generally regarded as difficult to examine and unsatisfactory to treat, are too apt to be classed among uninteresting cases, and to be discharged with some local wash.

When they are pale, puny, and deaf, with a constant nasal discharge, excoriated upper lip, and stuffy voice, the word "scrofula" finds a convenient application, and the children are kept indoors while cod-liver oil, iron, the iodides, or the hypophosphites are poured downward into the stomach, with but slight chance of reaching the seat of the trouble, which is upward, in the naso-pharynx.

In looking back upon my own special practice of a few years ago, I now feel that although typical examples of this complaint must have been seen, they were not properly observed, and certainly not properly treated. We need only reflect upon the importance of the naso-pharyngeal cavity to speech, its intimate relation with the organ of hearing, and, above all, its respiratory function, to be alive to the necessity of having it in a healthy condition. Imperfect nasal respiration in the child means imperfect health and imperfect development, with danger of permanent structural changes being excited in the middle ear or in other parts of the body.

The immediate and remote effects of adenoid vegetations depend chiefly upon the mechanical obstacle which they offer to the passage of air through the natural respiratory channels: namely, the nostrils and the naso-pharyngeal cavity. Hence the first symptom to attract attention in a child with this complaint is its difficult breathing, especially at night. This, in four of my cases, was noticed from birth, as well as difficulty in nursing, yet the cause was unsuspected, and it is doubtful if the diagnosis has ever been established in early infancy. One of these children had reached the age of six years when it first came to me through Dr. Clarence J. Blake, to whom she had been referred for deafness. It had, indeed, been under treatment at various times since infancy for symptoms shortly to be mentioned, and the diagnosis of "catarrh" had been pronounced; the prognosis being that the child would "grow out of it." Finally, a purulent discharge from the ears appearing, and the deafness increasing, the aurist was consulted and the true nature of the train of symptoms explained.

Such, briefly, is the story of numbers of these children. General practitioners are first brought into contact with them much oftener than specialists, and it cannot be too strongly urged that these obstructing growths, the removal of which marks an era in the life of the child, should be recognized and treated by them, or, at least, by the general surgeon. With a title of the attention paid to the naso-pharyngeal cavity which is given to other less important regions of the body, there would be no necessity for referring such cases to the specialists for either diagnosis or treatment.

The symptoms of this complaint vary in degree, according to the length of time the air-tract has been obstructed. In a child two years old, which, in my experience, is about the average age when trouble first begins, little else than difficulty of breathing, especially at night, and a dull, heavy look about the eyes, is noticed. An ordinary cold may have been the initial cause; the child soon shows a tendency to repeated attacks of "cold in the head," which increase in frequency and duration. These are accompanied by considerable nasal discharge, which, however, may be entirely absent when the child is free from the acute attacks. During the summer months there is comparative immunity from all the symptoms, yet with the return of fall and winter the colds recommence with renewed severity. Deafness, in the majority of cases, is soon added to the list of discomforts, and by the time the child has reached the age of six, eight, or ten years, the characteristics of a typical example of adenoid vegetations are as follows: The child is a mouth-breather. Its facial expression is dull and stupid; oftentimes idiotic. The open or half-

⁴ Tumeurs adénoïdes du Pharynx nasal, Paris, 1879.

open mouth is one of the most constant symptoms. Nasal breathing is interfered with during the day, but it is at night that this symptom displays itself with the greatest prominence. The child never sleeps soundly; it assumes unnatural positions in bed, and the slightest noise will awaken it. The labored breathing, especially when it has a fresh cold, is distressing to hear, and causes great alarm to the members of the family, who imagine the child is in danger of suffocation. The respirations will occasionally cease for a few seconds, and then re-commence with the same noisy, suffocative character as before, or the child may wake suddenly, bathed in perspiration, screaming and frightened. In the morning the cavity of the mouth is dry, and the lips may be parched. During the day the child is languid or irritable. The majority of the children are deaf, and their voices stuffy and thick. At school they are scolded by their teachers for inattention, and laughed at by their playmates. Yet the vacuous expression, open mouth, deafness, dead voice, nightmare, irritability of temper and lack of energy, all have a mechanical origin in the growths which are blocking up the naso-pharyngeal cavity and preventing nasal breathing.

The permanent condition of these children may be compared to the temporary discomfort of an adult in the congestive stage of a severe attack of acute coryza. And any one who has once experienced the relief afforded under such circumstances by the application of a spray of a four per cent solution of cocaine to the interior of the nostrils, may form a correct appreciation of the change which takes place in the dispositions and intellects of these little children after their naso-pharyngeal cavities have been made permeable to air. Moreover, when the growths are removed at one sitting, in the manner presently to be described, the improvement in the child will be immediate, especially as regards the character of the breathing, the quality of the voice, and oftentimes the hearing. And it is not long before their characters and facial expression undergo a complete change. It is true, as Prof. B. Fraenkel,⁵ of Berlin, says, "that the impairment of intellect and want of energy manifested by these children is real, and not merely in the expression of the countenance, is made evident after watching these same children after the growths have been removed. To the gratification and astonishment of the parents and teachers, the children hitherto sluggish and dull of comprehension now make rapid progress, and their comrades soon cease to make a laughing-stock of them. It seems, in fact, as if, through the removal of the obstructing vegetations in the naso-pharynx, they had become different beings."

Again, speaking of the nervous symptoms sometimes associated with this disease, such as abnormal sensations in the head, a feeling of weight and pressure in the upper and back part of the cranial cavity, melancholia, headache, etc., Professor Fraenkel continues: "The children come from school complaining of pain in the head, with a desire to lie down, and occasionally vomit, yet on the next day they have sufficiently recovered to go again to school. Slight fever sometimes accompanies these attacks. In many cases the parents and physician content themselves with the diagnosis of 'migraine' in explanation of these oft-recurring attacks. The children pass their holidays in the country or at some health resort, where

they are comparatively free from such attacks, yet they return home, bringing their old trouble with them. Then it is said, 'the child cannot bear the air of the school-room.' Finally, the adenoid vegetations are detected and removed, and the child is restored to perfect health."

The diagnosis of this complaint can be established with tolerable accuracy, even without direct examination of the naso-pharynx, from the train of symptoms already referred to, especially if the nostrils in front are free from obstruction, and if there are no enlarged faucial tonsils. Inspection of the cavity of the mouth will reveal almost invariably a high palatine arch, so marked in many cases as to be a deformity. The soft palate looks thick, and often seems to be bulged forward and immovable. Enlarged follicles are often seen on the posterior pharyngeal wall, and occasionally the uvula is relaxed. The faucial tonsils, similar in structure to adenoid growths (being, in fact, part of the lymphatic ring of the pharynx described by Waldeyer), are very apt to be simultaneously hypertrophied. Symptoms peculiar to adenoid vegetations have in former days been graphically described, but attributed wrongly to enlarged faucial tonsils. Dr. Henri Chatellier, of Paris, has called attention to this point in his recent interesting monograph.⁶ Adenoid growths in the naso-pharynx were unknown when Dupuytren (1824) and Alphonse Robert (1843) wrote their accurate descriptions of the evils which the pernicious habit of mouth-breathing entail, and which they considered to be due to enlarged faucial tonsils. Their account of the series of changes in mouth-breathers, such as impairment of hearing, alterations in the facial expression and in the quality of the voice, agitated sleep, obstinate cough, deformities of the bones of the face, nose, hard palate, dental arches, and of the chest-walls was exact and complete; but, as Dr. Chatellier observes, they mistook the real cause. The tonsil up behind the soft palate, which was not seen, was the real offender, and when it is removed, although the two lower tonsils may be enlarged, they will not impede respiration, and will, moreover, diminish in size after the naso-pharynx has been freed. Of the three tonsils, the third, or the pharyngeal tonsil, is the one that is causing the damage, and is the one to remove. Dupuytren himself remarked that excision of the faucial tonsils did not always relieve patients of their difficult breathing.

The change in the shape of the chest-walls in consequence of obstructed nasal breathing was strikingly shown in one of my cases, a boy nine years of age. He had suffered from his birth with labored breathing, difficulty in nursing when an infant having been one of the symptoms. When first seen by me, although his appetite was good, he looked ill-nourished and frail. His family history was good, and his three sisters healthy and robust. The appearance of this boy was brought about entirely through an insufficient quantity and a vitiated quality of air entering his lungs. His chest was thin and flat, the deep depressions of the intercostal spaces making the ribs appear unusually prominent, and, as his mother expressed it, in bathing the child it was like washing over a wash-board. At the lower end of the sternum there was a deep concavity. This boy's chest corresponded so perfectly with Alphonse Robert's description of this form of thoracic deformity, that I shall translate his

⁵ Deutschen Med. Wochenschr., No. 11, 1884.

⁶ Des Tumeurs adénoïdes du Pharynx, Paris, 1886.

own words.⁷ He says: "The lateral walls of the chest, instead of being round and regular, are, on the contrary, depressed, flat, sometimes even concave, as if at the period when the ribs were soft and concave they had been laterally compressed. This depression is more pronounced towards the middle of the thorax than at its summit or base. It is also more marked near the middle of the ribs than at their extremities. The vertebral column is but slightly altered; the costal cartilages form a projecting angle at the point of their attachment to the ribs. The sternum, in extreme cases, presents at its lower portion a deep depression." Dr. Chatellier offers the correct explanation of this deformity in considering it to be the result of prolonged indrawing of the chest-walls, due to an insufficient supply of air. It is an exaggeration of what is seen in cases of acute laryngeal stenosis in children, the picture of which is familiar to all.

To be certain of the presence of adenoid growths, in cases where posterior rhinoscopy is not practicable, the forefinger should be passed gently up behind the soft palate. Although not painful, the procedure is disagreeable, and as the child is apt to rebel against a second trial, it is important that the first attempt should succeed. To accomplish this, the child is not to be made to anticipate pain by being coaxed or cajoled; but without any unnecessary preliminaries, it is asked to open its mouth, which it will almost invariably do. The examiner, steadying the head by placing his right hand behind it, now passes his left forefinger rapidly, gently, but firmly up behind the soft palate. The information gained by digital examination is very characteristic. The growths will be felt as soft, velvety masses, which bleed readily, and on withdrawing the finger it is commonly covered with blood. The growths may not bleed, however, if the finger is not moved about much in the cavity, or kept there but a moment.

Simple as this procedure is, it requires some practice, and the examiner should also know how the normal, unobstructed naso-pharynx feels. The difference between the smooth walls of the normal cavity and one blocked up with vegetations is so marked as to leave little chance for error. But there is one source of self-deception for beginners which may be mentioned. Some children are naturally much more difficult to examine than others. Some contract their soft palate against the examining finger with such force as to impede its movements, and the contraction of the muscular fibres of the palate itself feels oftentimes like a circumscribed swelling; but it is merely necessary to remember that it is the posterior wall and vault of the pharynx that are to be examined, and not the posterior surface of the palatal curtain.

Given, then, a child with this affection, the question is: how are the growths to be removed? Removed they must be, for it is a useless expenditure of time to attempt to reduce the growths when they are of large size by local applications. Moreover, long-continued local treatment of the naso-pharyngeal cavity of little children is not feasible. Certain phenomenal children, it is true, are occasionally met with who are tractable and submit to whatever is done to them, but they are obliged to come to the physician again and again, and always do so with fear and dread.

Yet most little children it is impossible to treat at

all. I have, therefore, long since abandoned all attempts to treat this affection unless the child is anesthetized. There are no contra-indications to the administration of ether for operations in the naso-pharyngeal cavity, and when adenoid growths are present in large masses their complete removal is too painful for children without anesthesia, as well as unsatisfactory for the operator.

In advocating the method for the removal of these growths, which has become my routine practice, I shall bear in mind Sir William Dalby's admonition, who, in writing⁸ on this subject, says: "If one thing more than another stands out in relation to what is written, said, and done in connection with this matter, it is the necessity of tolerance for other methods while advocating our own, and for the following reason: That it is characteristic of the complaint that if the growths are removed in any way, so long as they are completely removed, the patients get well both as to nasal breathing and hearing."

There are so many gradations in the size, toughness, and quantity of these growths, that I am inclined to believe that different operators, in extolling some particular method for their removal, have in mind only one form of the complaint; and while their particular procedure is applicable for certain cases, it is entirely impracticable for others.

The method I consider the best for a child when there is a large mass to be removed, and which I have carried out with great satisfaction in 104 children of ages ranging from twenty months to fourteen years, is as follows: The child is thoroughly etherized. It is then placed in a good light, and seated upright in the lap of an assistant, the operator being seated opposite to it. The child's mouth is held open by a small-sized mouth-gag inserted between the teeth on the right side. Any accumulation of mucus in the pharynx is to be wiped out. The operator should now pass his index-finger up behind the soft palate and assure himself of the quantity and situation of the growths. Then gently pulling the soft palate forwards and upwards by means of a palate-hook held in the left hand, a pair of post-nasal forceps, held in the right hand, is introduced, closed, into the naso-pharyngeal cavity. One soon learns to feel the growths with the closed end of the forceps. The blades are then opened, the mass grasped, and pulled off either by direct traction or by a slight twisting movement of the forceps, but under no circumstances is force to be exerted. If the growth comes away with difficulty, release the blades of the forceps and begin over again, taking hold of a smaller portion of the growth. Force, as well as hurry, is to be avoided. The rapidity with which the operation is completed depends upon the amount of the hemorrhage. If there is much bleeding after a portion of the mass has been removed, wait until it has ceased, and then proceed with the operation. This it is usually necessary to do from three to six times or more before the cavity is cleared out. The finger is to be inserted in the cavity from time to time, until it is found that it is practically free. When it is considered that enough has been accomplished with the forceps, I hold the child's head well forward, so that the blood may flow out of the nose, and with the ball of the index-finger of the left hand and the finger-nail, attempt to smooth down the remaining ragged edges by passing the

⁷ Bulletin général de Thérapeutique, t. xxiv, 1843, p. 343.

⁸ The Lancet, October 2, 1860, p. 618.

finger first into one choana, then into the other, and then backwards and downwards along the posterior wall of the naso-pharynx; also, when necessary, along the lateral wall of the cavity, the Eustachian prominence, and in the fossa of Rosenmüller. This manipulation with the finger causes the blood to flow more freely than the previous evulsions with the forceps. Occasionally, also, after the larger portion of the growths has been plucked off with the forceps, a post-nasal curette may be introduced behind the soft palate and the remaining ragged masses scraped away. The steel finger-nail fixed to the finger and used as recommended by Sir William Dalby, is also serviceable for this purpose. In certain cases, Meyer's ring-knife introduced through the nostril is of use to scrape around the Eustachian orifices, the end of the instrument being guided by the forefinger behind the soft palate, as practised by Mr. Butlin,⁹ of London, whose method, in fact, of dealing with these growths, with the exception of the position of the patient and the management of the soft palate, does not differ very materially from the one described. But, as a rule, the happiest results may be accomplished with the forceps and the forefinger alone. With proper care and assistance there is no danger for the child, and in one sitting, occupying from ten to twenty minutes, it is practically cured of a complaint which may have existed for years.

The removal of the growths, however, is not accomplished in all cases with equal satisfaction. The conditions which make the operation difficult are an excessive amount of mucus in the throat, a large, thick tongue, enlarged faucial tonsils, a long distance from the lips to the posterior pharyngeal wall, a small space between the free border of the palatal curtain and the pharynx, and a deep naso-pharyngeal cavity. In no case has it been necessary to repeat the operation, though in two children, where the operation was prolonged, owing to some complication, it was thought at the time that a second sitting would be needed. Yet these children did perfectly well, which leads me to think that we need not be too energetic, or imagine that every particle of the growths must necessarily be brought away. The principal object of the operation is to establish free nasal respiration. If this be effected, a small amount of adenoid growth left behind may not do harm. The vitality of the remaining tissue is probably destroyed, and it will atrophy.

The growths do not recur after removal. In operating, as I invariably do, with the child in the upright position, it will be urged that there is danger of blood being sucked into the larynx. In speaking with practical surgeons concerning the operation this criticism has almost always been advanced. But the objection is theoretical, and with care and prudence no accident of this nature need be feared. There are no large bloodvessels in the naso-pharyngeal cavity to be wounded, and it is characteristic of the bleeding from the growths that it ceases completely in a few moments. The blood does not come with a gush, but will be seen to be trickling slowly down the posterior wall of the pharynx. That which is not sponged out flows into the stomach, and will be vomited later. Liquids naturally flow down the œsophagus, and not down the windpipe. The danger in operations about the mouth is from a clot of blood becoming wedged in the glottis, and it is easy to guard against its for-

mation in this operation. The bleeding varies greatly in different cases, and, as far as I am aware, there is no way of foretelling in any given case how profuse the hæmorrhage may be. The vascularity of the growths does not seem to be proportionate to their size, for some of the largest masses have bled insignificantly. In beginning the operation, go slowly and watch. When a portion of the growth has been removed, wait until the bleeding has ceased, and then proceed with the operation. These children with obstructed noses, especially if they happen to have enlarged faucial tonsils, are usually bad etherizers, and in many the accumulation of mucus in the lower pharynx is excessive, all of which is calculated to make the operator feel anxious; but no annoyance in any case has been caused by blood in the windpipe, and no surgeon who has been present at the operations, either at the Massachusetts General or the Boston City Hospital, or in my private practice, has seen cause for alarm on this score. There is more to be feared from vomited food lodging in the larynx than from a clot of blood. The ether, therefore, should be administered on an empty stomach. The degree of etherization must be sufficiently profound to abolish reflex action of the soft palate, so that it will yield to being held forward by the palate hook without resistance. It is important to keep the palate out of the way of the forceps, and no effort should be made to grasp the growths when it is contracted. For should its posterior surface or other healthy wall of the cavity be nipped, an obstinate and annoying hæmorrhage may take place. It will be an advantage for the operator to have a small index-finger; also a light hand and a delicate touch. It need hardly be said that he should possess a perfect familiarity with the situation of the different anatomical structures in the naso-pharyngeal cavity, and know the difference when feeling with the finger or with the forceps between the parts in a normal state and when covered by adenoid growths. In selecting a pair of post-nasal forceps for the operation, it will not do to take the first pair that comes to hand. The average instrument in the shops is unnecessarily cumbersome, and unnecessarily long. For children, the curve of the cutting end of the forceps should be small, and the length of the handles as short as possible and perfectly firm, so that when the cutting ends are in contact there will be no "give" at the handles. The ease and success with which these growths are removed under ether, where the sense of touch plays such an important part, depends very much upon the proper selection of instruments. The accompanying drawing shows the exact size of forceps¹⁰ which have been found to be the most serviceable for the average child up to the age of fourteen. The conventional hard-rubber palate-hook is also shown, as well as the mouth-gag preferred, which is easy to adjust, easy to remove, easy to keep clean, and never out of order.

With regard to the amount of this over-growth of glandular tissue which may be contained in the naso-pharyngeal cavity, it can only be said that it varies according to the size of the cavity; and this is subject to as wide variation in the child as in the adult. Children of the same age, therefore, having the same amount of adenoid hypertrophy, may present different symptoms of the complaint, owing to the relative capacity of their cavities, and consequently to the de-

Actual Size of the Three Instruments.

gree with which nasal respiration is obstructed. In one case the clinical picture would be complete, while in another deafness might be the only prominent symptom, owing to the situation of growths around the Eustachian orifices and at the pharyngeal vault, the large size of the space giving sufficient breathway.

The two cuts on the next page, photographed from the original specimens, and showing the exact size of the bottles, will give an idea of the quantity which may be taken out of a child's naso-pharynx.

Specimen No. 1 shows the largest amount removed at one sitting in any case, while No. 2 represents an average amount in typical cases about the age of eight years. Specimen No. 1 came from a negro fourteen

years of age, yet who had the appearance of a puny boy of nine. His breathing had been obstructed from his birth, and from the age of nine months there had been practically no nasal respiration. Apart from the color of this lad he had none of the facial characteristics of the black race. His nose was small and pinched; his face long and undeveloped. His mouth, day and night, was wide open, and each breath noisy. At night his struggle for air, from the description of his parents, must have been terrible. He was etherized and operated upon in the manner described. The naso-pharynx was literally packed with adenoid growths. The bleeding, however, was surprisingly slight, the growths being very soft and coming away with ease, hanging in large pieces between the blades of the forceps. As the operation progressed the breathing became better and better, and when the cavity had been completely freed, the change in the character of the respiration was most striking to all present. From being noisy and labored it had become free and peaceful. But this improvement in the breathing led to a new cause for alarm. The first night after the operation the boy slept so quietly that his parents could not persuade themselves that he was not dead, and went repeatedly to his bed to reassure themselves. They were actually kept awake by the absence of the noise which had disturbed them so many years. This is the only instance of the disease which I have met in the black race, and I was inclined to attribute the amusing account given by the parents of their experiences on the night in question to the mental peculiarities of the negro, and that it was based on ig-

norance and exaggeration. But another case, belonging to an entirely different station in life, recently operated upon, gave rise to the same kind of alarm to a near relative of the patient.

The patient was a girl nine years of age, and had always been under the special care of an older sister. Although the child had been a mouth-breather for five years her hearing was unaffected. Her breathing at night, according to her sister, who always occupied the same room, was distressing to hear. She was restless and liable to awake at the slightest noise. When taken with a cold she became feverish and slightly delirious. At such times she had to be propped up in bed with pillows, her breathing being of such a character that the sister feared the child was in danger of suffocation, and she often lay awake in anticipation of some accident, her chief guide being the noisy respirations. The sole cause of this child's trouble was a large adenoid growth completely obstructing the respiratory channel. After its removal her sleep became immediately so calm, sound and natural that the sister, not being able to accustom herself so rapidly to the change, found difficulty in convincing herself that the child was breathing at all, and was considerably exercised for three nights after the operation.

The treatment of a child in this condition is followed, not only by the cure of the patient, but by the restoration of peace to the whole household. Another good effect of the operation which may be noticed at once is the change in the quality of the voice. The first words the child speaks, in certain cases, are clearer, the resonating properties of the cavity being restored through the removal of the growths. This improvement is especially prominent in the singing voices of some children.

It is also surprising how soon the whole expression of the countenance changes. The mouth generally remains closed as soon as the nasal air-tract is made free, and the lines which have been formed at the angles of the mouth, nose, and corners of the eyes by the weight of the hanging lower jaw disappear very rapidly. In some of the children operated on more than a year ago, the improvement in their physique is most remarkable. The subjoined pictures will show the changes in three instances which have taken place after operation, and it is no exaggeration to say that the dispositions of these children undergo as important a change for the better as is manifested in their personal appearance.

Among the most gratifying results of the operation is its influence upon the restoration of the hearing. Of the 101 children operated upon, 47 have been in private practice. Out of these 47, 39 have been deaf. The majority of them have come to me through the advice of Dr. Blake, who has kindly consented to review this branch of the subject, and whose paper on the "Relation of Adenoid Growths in the Nasopharynx to the Production of Middle Ear Disease in Children" will be found in this issue of the JOURNAL.

The after-treatment is very simple, and, as a rule, there is nothing to be done beyond taking precautions

to keep the child from catching cold. In winter, or in stormy seasons, the children should be kept indoors for a week, but in summer they may be allowed to go out and lead their natural lives as soon as they have fully recovered from the effects of the ether, or from any weakness due to the loss of blood. These points must be determined by the peculiarities of the individual children. Of my 104 cases, three, who had had previous trouble with the ears, developed an acute attack of inflammation of the middle ear; and one, on the sudden restoration of the hearing, suffered for weeks with a severe form of chorea. With these exceptions, there has been no accident to record due to the operation, nor is it followed by any shock. It is usually necessary to administer a large quantity of ether, and as soon as its effects have passed off, the patient may be said to be practically well. As a rule, the children breathe, sleep, and feel better than they have ever felt in their lives, and it is often difficult to restrain them and keep them in the house. Their regular diet may be taken, for, except in rare instances, there is absolutely no pain on swallowing in consequence of the operation. In fact, the children do not know that anything has been done to them. The absence of pain on eating after an operation on the "throat" where such large masses are removed, and attended occasionally by so much hemorrhage, makes a great impression upon those who are not acquainted with the situation of the growths, or with the physiology of deglutition. If any after-treatment is needed, it will consist of tonics and a detergent wash locally for the nose.

The foregoing remarks have intentionally been confined to the practical side of this complaint; namely, to the importance of its early recognition in children and its treatment. The removal of these growths, however, is not alone essential to the good health and personal appearance of children, for their indelible traces are often seen in adults. Although this glandular tissue tends to disappear after the age of puberty, it may be

present in such large quantity as to lead to permanent damage before that period arrives, and its marks will be carried through life. Dr. Chatellier (loc. cit.) has called attention to the deformities of the bones of the head and face which result from neglected adenoid growths. He points out that the air-cavities, as the frontal, sphenoidal, and ethmoidal sinuses, and the antrum of Highmore, being normally in communication with the air, cease to develop when the circulation of air through the nose is interfered with, and hence the dimensions of the face are altered. The lower jaw, which follows its normal development, often protrudes over the upper jaw, which is contracted in front, the upper lip is drawn up, while the hard palate, from the constant atmospheric pressure within the mouth, is pushed upwards, terminating in a sharp angle, like the Gothic arch. It does not seem at all unlikely that the many cases of deafness in adults due to ankylosis of the ossicles, or other structural changes in the middle ear, and which are associated with the V-shaped palatine arch and contracted upper jaw, are the remains of these adenoid growths which accomplished their destructive work in early life undiscovered and unsuspected. The relation of this complaint to certain cases of deaf-mutism must be for future observation and experience to determine.

Dupuytren in his "Mémoire sur la Dépression Latérale des Parois de la Poitrine,"¹¹ says that no disease ever presented to him a more painful spectacle than that of an infant who had the parietes of the chest pressed in laterally, enlarged tonsils and violent whooping-cough. It experienced at each crisis of the cough such oppression that instant death seemed to be threatened; it did indeed in one of the paroxysms. That adenoid growths in the naso-pharynx were at fault in this instance, there can be but little question. Provided the naso-pharyngeal space be unobstructed, enlarged faucial tonsils cannot seriously interfere with inspiration, certainly not to the extent of producing the deformity of the chest walls described by the French writers already mentioned, also by Coulson,¹² of London, and by J. Mason Warren,¹³ of Boston. The children seen by Dupuytren "suffering under depression of the sides of the chest and enlarged tonsils at the same time, and who fell, after violent but useless efforts to breathe and after cruel suffering, into the most alarming state of convulsion, or into a state of suffocation, amounting to asphyxia from which state they recovered only to fall again into the same danger at the end of a few minutes," were the victims of adenoid vegetations.

It is apparent that the ravages of scarlet fever, diphtheria and measles, are more severe in children if these growths happen to be present. The various reflex phenomena, also, which may take the form of a true chorea minor, as Dr. A. Jacobi¹⁴ has observed, and for which the naso-pharyngeal cavity is responsible, should impress upon us the influence of this region upon the well-being of the child, and the importance of paying attention to it. Its most frequent affection in children is the one we have been here considering, and I can only repeat, what I said in my first paper on this subject, that there is no other disease in the domain of him who confines himself to the upper respi-

ratory tract, the treatment of which is attended with more satisfaction to the operator, or with more permanent relief to the patient. If the results in all children are not equally good, owing to more or less permanent damage before the removal of the growths, the operator has at least the gratification of restoring to the children a permeable air-tract.

RELATION OF ADENOID GROWTHS IN THE NASO-PHARYNX TO THE PRODUCTION OF MIDDLE EAR DISEASE IN CHILDREN.¹

BY CLARENCE J. BLAKE, M.D.

THE subject of adenoid growths in the naso-pharynx and their effect upon the organ of hearing has been so well treated by Meyer,² Loewenberg,³ and others, that the present paper must, in justice to these acute observers, be regarded rather as a recapitulation, the motive for which is that, in view of the large number of cases of this class among children, attention cannot be too widely drawn to a cause of aural disease often unrecognized, and when once found easily removable.

The fact that the artist Catlin⁴ was led to classify and contrast the so-called mouth-breathers among whites with the nose-breathing American Indians among whom he lived and sketched for many years, is sufficient evidence of the recognizable existence of such a class in our community, although the local cause of what he stigmatizes as a vicious habit was not appreciated by him, or indeed by any physician even, so far as we have record, until Czernak signalized the invention of his method of rhinoscopy by the discovery of these glandular tumors.

That Catlin's artistic eye should have been offended by the distortion of the human face which he so graphically portrays is to be expected, but he also mentions impairment of hearing among the accompaniments of the "bad habit of mouth-breathing."

Since the organ of hearing is the channel through which, pre-eminently, in childhood the stimulus to mental development comes from the outer world, a fact of which we have ample evidence in the results both of physiological experiment and clinical experience, and since the enlargement of Luschka's glands is a disease of childhood particularly, though its consequences may continue through adult life, a recognition of the relation which this disease bears to the hearing power is of great importance.

The presence of adenoid growths in the naso-pharynx affects the organ of hearing and its function mainly in two ways — by interference with the ventilation and with the blood-supply of the middle ear. To clearly review the manner of this interference it is well to consider the means provided for continuing a definite supply of air in the middle ear, and for maintaining a just balance of the arterial and venous circulation in that part of the organ of hearing which suffers most immediately from the filling of the naso-pharyngeal cavity and consequent closure of the Eustachian tube. This passage, the Eustachian tube, which is both drain and ventilating shaft, is in the

child both shorter and wider than in the adult, its tympanic orifice is comparatively large, but the pharyngeal orifice is indicated only by a slight depression or fissure in the lateral pharyngeal wall, and the posterior prominent portion of the tube which forms a decided projection in the adult is hardly noticeable.⁵ The former of these anatomical conditions, as is evident, favors rapid recuperation after restoration of patency of the Eustachian tube, and the latter renders that passage much more easily occluded at its faucial end by the pressure of any substance filling the naso-pharynx. The constant permeability of the upper portion of the Eustachian tube has long been a question actively and ably discussed on both sides for and against, but the weight of evidence is now in favor of the view that the Eustachian tube is not a constantly open ventilating shaft for renewal of the air in the middle ear. As the air in the middle ear is being absorbed constantly, with greater or less rapidity according to the state of the circulation in the mucous membrane, its renewal must be provided for by gaseous interchange,⁶ or by the operation of such mechanism as shall, by opening the Eustachian tube, and at the same time causing increased atmospheric pressure in the naso-pharynx, assure the ventilation beyond peradventure.

This process, in which the acts of deglutition and of phonation play an important part, is provided for through the operation of two muscles, the levator and tensor palati molles, both of which are double-action muscles, being attached at the one end to the soft palate, and at the other to the anterior and inferior walls of the Eustachian tube. Each voluntary movement of the soft palate, therefore, is accompanied by the contraction of the palatal ends of these two muscles, and by a corresponding movement at the tubal ends, the result being a withdrawal of the anterior from the posterior wall of the Eustachian tube, and at the same time a depression of the inferior wall or floor of that passage giving it a greater inclination downward toward the pharynx. The same movement which opens the Eustachian tube, by lifting the soft palate, tends to compress the air in the naso-pharynx, and so favors still further the ventilation of the middle ear.

The same simultaneity of action, and the same effect in a lesser degree, is found in phonation. In the production of all the consonant sounds, with exception perhaps of the sibilants, there is more or less back pressure, pneumatic pressure in the pharynx and naso-pharynx, while with all the back consonants so-called, *k, g*, for instance, there is in addition a very strong and decided muscular contraction of the soft palate, as shown by the very interesting tracings made with the palate myograph,⁷ and in the use of the glosso-graph of Amadeo Gentili. Control experiments made by the writer in cases of perforation of the membrana tympani by means of manometres placed in the ear, and in cases of manometric cicatrices of the membrana tympani by direct observation of the movements of the cicatrices show that there is a decided increase of air pressure in the middle ear coincidently with the pronunciation of the consonant sounds, and most markedly with *m n ng* and the back conson-

ants, while the forcible expulsion of air and the elevation of the soft palate in crying produces movements of the manometric cicatrices which show that this operation tends also to assist materially in the process of ventilation of the middle ear. In addition to these more active provisions for this purpose, namely swallowing, speaking, crying, and the numerous co-ordinate muscular movements of the throat, there are the passive movements of the soft palate and the changes of air pressure in the middle ear, which occur during sleep with each respiration.

With the presence of a growth in the naso-pharynx this admirably working mechanism is interfered with, and even if the growth is not sufficiently large to occlude the faucial orifices of the Eustachian tubes, it interferes with the palatal movements, and with the proper balance of air pressure in the naso-pharynx, and is inevitably productive of injury to the ear, the result of the decreased air pressure being the production of a partial vacuum in the middle ear, with its consequent train of congestion, swelling of the mucous membrane, and trophic changes of greater or less permanency according to the duration of the abnormal condition. That it is not necessary that the growth should be a large one to influence the ear is shown by the effect which a small growth has upon the pronunciation of all the nasal consonants; that is to say, upon the palatal movement. Where the growth is large and exerts considerable pressure on the walls of the naso-pharynx, there is in addition to the consequences already mentioned an effect directly upon the blood-supply of the Eustachian tube and middle ear by interference with the return of the blood from the middle ear through the tubal into the lateral pharyngeal veins.

A portion of the blood-supply to the anterior and superior portions of the tympanic cavity and to the membrana tympani comes through a small artery running along the upper walls of the Eustachian tube, the blood so supplied being returned in part through veins running superficially downward in the tubal mucous membrane. Mechanical pressure on the lateral pharyngeal wall, in the neighborhood of the Eustachian orifice may therefore result in a blood stasis in the middle ear, and in an objective condition similar to that admirably described by Boucheron, as seen by him in certain cases of so-called deaf-mutism in children whom he relieved by catheterization of the Eustachian tube. The description by Boucheron of a membrana tympani, dull, greatly depressed, and of the deep blue-red color indicating venous congestion of the middle ear, appearances markedly seen in some of the cases which suggested this paper, permits the supposition that in some of his cases, also, he had to deal with the results of adenoid growths in the naso-pharynx.

The train of aural symptoms which come from the presence of adenoids are, therefore, such as would result from interference with the normal ventilation and nutrition of the middle ear tract, and are more or less permanent, according to the duration and size of the adenoid growths.

In the earlier stages, when the growth is small, the ear is noticeably affected only when, in addition to the bulk of the growth in the naso-pharynx, there is added the encroachment upon the space of that cavity by swelling of the mucous membrane, accompanying so-called head-colds. As the growth increases less

⁵ Politzer, *Lehrbuch der Ohrenheilkunde*.

⁷ A new method of studying the motions of the soft palate, Dr. Harrison Allen. *Phila.*, 1884.

and less swelling effects the deleterious purpose, and the intervals of freedom from impaired hearing, nocturnal ear-ache, and subjective noises in the ears become shorter and more rare. In the meantime changes are taking place in the structures of the middle ear which are more or less permanent; the preponderating pressure on the outer surface of the membrana tympani pressing that membrane inward, and allowing the relaxed tendon of the musculus tensor tympani to contract and hold the malleus, and with it the membrana tympani, in its abnormal position, tends, as does also the thickening of the mucous membrane, to permanently impair the mobility of the sound-transmitting mechanism of the middle ear, or, as is seen in some cases, the impairment of nutrition, lowering the vitality of the delicate tissues in the middle ear, an ulcerative and suppurative process is easily set up under the necessary additional provocation.

In some of the cases mutually observed by Dr. Hooper and myself there was suppurative inflammation of the middle ear, which first showed any gratifying response to local treatment only after the removal of the adenoid growths.

In reference to the aural symptoms, the cases under consideration may be divided into three classes. The first includes those in the earlier stages of the adenoid growths, which have had occasional ear-ache and the occasional impairment of hearing apparently readily referable only to what is called a head-cold. These children have very variable hearing, are frequently accused of inattention and disobedience, and are either too young to know, or have too slightly noticeable an impairment of hearing to appreciate that their derelictions are sins of the flesh and not of the spirit. The effects to the ear of the removal of the growth in the naso-pharynx are often appreciable only to the trained observer; the child is freed from a catarrhal affection, and the improvement in hearing, if any is noticed, is taken for what it is, a matter of course. An objective examination of the ears, however, shows that there is no longer a slightly congested condition of the tympanic mucous membrane, and in the course of time the thickening of the mucous coat of the membrana tympani is seen to be decreasing. In the second class are the more advanced cases, in which, the preliminary stages being passed, the impairment of hearing and the structural changes have become recognized as fixed facts, the impairment of hearing in some of these cases being so great and so persistent that the child is regarded either as a deaf-mute, or even as idiotic, the well-known effect of obstruction of the hearing upon the mental development favoring the latter supposition. In many of these cases it has been found that catheterization of the Eustachian tubes, the air douche proving ineffectual on account of the blocking of the Eustachian orifices and interference with the movement of the palate by the growth, has decidedly and immediately improved the hearing, and entirely changed the objective symptoms in the ear, the membrana tympani, previously dull both in color and in lustre, returning to the normal appearance in a greater or less degree in both respects.

The improvement in both appearance of the ear and in hearing power in these cases, consequent upon the use of the Eustachian catheter, is, however, but temporary, the true cause of the abnormal condition remaining.

In by far the largest majority of such cases the removal of the adenoid growths is followed by an immediate and gratifying improvement in hearing, which in some of them remains unabated. In others, however, the impairment is again noticeable at the end of a few days. In all of these latter cases there is accompanying, and as a result of the adenoid, a considerable swelling and congestion of the naso-pharyngeal and tubal mucous membrane, enough in itself to interfere materially with the physiological action of the Eustachian tubes. The free bleeding following the operation upon the adenoids sufficiently depletes the swollen mucous membrane to bring about a condition of freedom for the middle ear temporarily, which is permanently attained subsequently only by patiently continued treatment.

To the third class belong those cases, already alluded to, in which suppurative otitis media is a result of the disease in the naso-pharynx plus some local exciting cause, or is merely a coincident of a suppurative disease of the middle ear of other origin. That the maintenance of patency of the Eustachian tube is an important factor in the successful treatment of these cases is well recognized, and in at least two of the cases which are the subject of this joint memoir, the effect of the removal of the adenoids upon the response of the ear to the same treatment which had been previously pursued was most gratifying.

A classification of the cases mutually observed and operated on under either by Dr. Hooper, which are the only ones here included, shows that out of the whole number, thirty-nine, or nearly eighty-three per cent., had evidence of more or less implication of the ear, and that of that number in thirty-five, or nearly ninety per cent., the result as evidenced by the improvement in hearing was eminently satisfactory.

Comment upon the importance of a recognition of these cases, and the application of an early remedy, is, in view of these and similar results of other observers, and of the known consequences to the hearing in later life, of the persistence of these abnormal conditions, quite unnecessary. It is well to bear in mind, however, that with the removal of the adenoid growths the work—as regards the ear—is not entirely done, and that the rhinologist and otologist must act as friends in council; the removal of the cause is the first step, it is true, but, though as Dr. Holmes says—and this seems especially true of children—"Nature is kinder than the doctors think," some assistance is needed in many of these cases to help on the removal of the consequence of the cause.

NOCTURNAL INCONTINENCE OF URINE.¹

By E. M. BUCKINGHAM, M.D.,
Instructor in Diseases of Children, Boston Polytechnic.

THE subject of nocturnal incontinence of urine in children is of interest both from the obscurity that sometimes surrounds its etiology, and from the great annoyance to which it subjects the patient and his friends. It is a symptom, and, like many other symptoms, does not always depend on one and the same cause.

Aside from cases depending upon deformity, upon

¹ Read before the Boston Society for Medical Observation, February 6, 1888.

reflexes from outside the bladder, as phimosis or pinworms for example, or from calculus within the bladder, or an abnormal quantity or quality of the urine, causes which all together, probably exist in but a minority of the cases; writers on the subject seem to recognize quite commonly that the immediate exciting cause may be either an over-sensitive condition of the expelling muscles, or atony of the sphincter of the bladder. This explanation is of course only partial, it being still incumbent on us to explain the course of atony or over-sensitiveness. In looking over the record of the Medical Out-patient service of the Children's Hospital I find that of twenty-six cases applying for treatment there since early in 1883, five only have presented themselves in the six months April to October, while twenty-one have appeared from October to April, possibly because of greater perspiration in summer, and consequently fuller bladders in winter. The disparity is even more striking when one considers that the clinic is larger in summer, and, however explained, it certainly suggests weather as having an influence in the matter.

As my own service in this hospital has been until recently confined to the months in which these cases apply least frequently, I can say nothing learned from this source, nor have I had the time to study the records of the other out-patient rooms accessible to me. My recollection, however, is very strong that in the years when I was annually in charge of the children's room of the Boston Dispensary, for three of the winter months there were a number of debilitated anæmic children suffering from incontinence who were speedily relieved, for a time at least, by the use of iron. This is perhaps less likely to be the case in the better class of patients seen in private practice, and such an explanation accounts for their not being recognized by some good observers of considerable experience. I cannot recall any private patient of my own successfully treated by iron, although I have used it a few times.² These debilitated cases in so far as I can see, are as likely to have irritability of one muscle caused by their debility as atony of another; but it appears to me to be good practice to attempt the restoration of their health before beginning the use of sedatives, especially so as that may be all-sufficient, and as the prolonged use of sedatives, while often necessary, is not a thing to be lightly entered upon with a debilitated child.

The following case illustrates, to my mind, the existence of debility as a cause of nocturnal incontinence:

A not very strong boy of nine years had had for a long time attacks of incontinence at night, which had been relieved by belladonna or atropia, but which always returned after a time. When the course which I am about to describe began, the trouble had lasted for some little time, and the accidents were of nightly occurrence. He was given a solution of atropia in acidulated water, one grain to the ounce, making each drop contain gr. $\frac{1}{16}$ of atropia. Of this was given one drop for the first two doses, two drops for the next two, three for the next two, and at the seventh dose four drops, equal to gr. $\frac{1}{16}$, there being three doses in the day. At various times it became

necessary to stop the progressive increase of dose because of malaise or intestinal disturbance, or some symptoms more certainly attributable to atropia, but on the whole the medicine was pushed, except when some results, good or bad, indicated a stop.

When the dose equalled gr. $\frac{1}{16}$ incontinence occurred only once in every few days instead of every night, but there was some thirst, and the pupils were less active. The morning dose was then omitted, that at noon lessened, and the increase of evening dose went on, this increase stopping with temporary improvement, and beginning again with failure, until gr. $\frac{1}{8}$ was given at noon and at night, with the effect of giving a respite of nine successive nights. By this time, about two months from the beginning, the child was far from well. He was dull, with coated tongue, poor appetite, and dilated pupils. A bright red rash appeared for a few hours.

The night dose was then retained and the others omitted, a drop of tr. of nux vomica being substituted in the morning, that being a tonic that always agreed with the patient. Soon the night dose was reduced drop by drop, until, after ten days of a single daily dose, it being then gr. $\frac{1}{8}$, he wet the bed. The child looked very badly, with a very dry skin, and an absolute distaste for food. Fourteen nights had been the greatest success, and the use of atropia was stopped. Five nights passed without accident, and then incontinence gradually returned. The child was under treatment for another month for gastro-intestinal disturbance, with a general venous condition and a dry skin, none of which existed at the beginning of treatment.

During the following two and a half years the condition was much the same as before this course was begun; that is, he was a rather puny boy, with a whimsical appetite and possibly rather less incontinence than before, but never going over four nights without an accident. During this time he several times got nux vomica as a tonic.

Then an attempt was made with faradization from just above the sacrum to the perineum for four minutes at a time, every fourth day, he having in all six sittings. Perhaps this was not long enough for a fair experiment. At any rate he never went over three nights without accident, while without electricity he had sometimes gone four.

Shortly after this he went on a long summer vacation, learned to swim, I think, was out of doors all the time, and returned in the autumn nearly well, improvement having been gradual. More than two years later I learned from his mother that there had been no return of his trouble. At the same time the general improvement in physical condition and increased delight in out-of-door sports was something remarkable.

I am well aware that this case may be differently interpreted by different minds, but it is to be observed that the child was a weak one, that the case was severe and of long continuance, that there was no improvement during the use of electricity preceding the vacation; and that improvement, when it did come, came step by step with greatly improved physique, and was complete in a few months; and that, as the child was only eleven, one can hardly attribute recovery to the approach of puberty, as is sometimes done.

This case, in connection with those of relief closely following the use of iron, seems to suggest at least a

² Since the above was written, I have been able to relieve a private case of long standing, by the use of iron alone. The child being in good circumstances but rather anæmic. E. M. B.

possible lesson, and my apology for presenting them to the society is that there are, as before said, some good observers, of experience, who think that they have seen little or no result from treatment directed to the general condition alone.

Reports of Societies.

BOSTON SOCIETY FOR MEDICAL OBSERVATION.

CHARLES P. STRONG, M.D., SECRETARY.

MEETING February 6, 1888, Dr. C. F. FOLSON in the chair.

Dr. F. H. HOOPER read a paper on

THE DIAGNOSIS AND TREATMENT OF ADENOID VEGETATIONS IN CHILDREN.¹

Dr. C. J. BLAKE supplemented the paper with

REMARKS UPON THE RELATIONS OF THESE GROWTHS TO DEAFNESS.²

Dr. E. D. SPEAR thought that he could add little in supplementing the instructive papers of Drs. Hooper and Blake, but wished to show photographs, taken by himself, of several cases in which adenoid disease of the naso-pharynx complicated various forms of disease of the middle ear, causing the peculiar appearance of the child's countenance referred to, and explained in Dr. Hooper's paper.

In the removal of the growths he had followed Sir Wm. Dalby in using the finger-nail, and in the majority of cases with success, though it was usually necessary to repeat the operation.

Marked improvement immediately followed the operation, both of the ear and throat symptoms.

Dr. Spear showed a "steel finger nail," which was suggested by Dalby's, but which was to be used upon the back of the finger, thus leaving its palmar surface free to feel the growth. He did not advocate its use, however, because cases requiring forcible scraping were best treated after Hooper's method, with anaesthesia.

Dr. KNIGHT said that the paper and experience of Dr. Hooper were very valuable contributions to the subject of adenoid hypertrophy in young children and its proper treatment, and that it might not be improper for one familiar with the subject to indicate in just what direction Dr. Hooper's communication was of much practical value.

In the first place, the large number of cases reported by Dr. Hooper, taken in connection with the large experience of Butlin, in England, and Hoffman, of Germany, to say nothing of the lesser experiences or others, should set at rest the fears of removing adenoid hypertrophy at the vault of the pharynx during general anaesthesia. There had been great dread when this was first proposed, and by none more than by surgeons familiar with anaesthetics, that blood would run into the larynx in such quantity as to produce danger of suffocation by spasm, or otherwise. Experience has shown, however, that the reflex excitability of the pharynx being retained, the blood is swallowed, and often vomited afterwards in large amount.

In the second place, Dr. Hooper's cases were evidence that the removal of the growth could be effectually performed under general anaesthesia, and without the aid of the rhinoscopic mirror. The contrary of both these statements had been quite recently made by eminent authorities. In regard to the latter point, a recent text book had declared that operations on the adenoid should never be attempted except the forceps were guided by the mirror.

In most cases of young children we have either got to make the diagnosis and carry out the treatment by the sense of touch alone, or let them go without either.

In the third place, Dr. Hooper's experience shows us that the number of cases of adenoid hypertrophy requiring relief is much larger than is generally supposed. It is only another instance of the fact that we don't see a thing until we look for it. A distinguished clinical teacher and writer in a paper on the relation of diseases of the throat to those of the ear, had said within a very few years that he had never seen a case of deafness due to adenoid hypertrophy! If he had examined all the deaf children who had come under his observation, using digital exploration when rhinoscopy was impossible, with reference to this one point, he would undoubtedly have found many.

Just what cases should be operated on, and just what cases can be left for the natural atrophy is not yet decided, but there can be no doubt about not only the propriety, but necessity, of operating, in case deafness is already present, or when the child is afflicted with serious nervous symptoms, deprivation of continuous sleep, etc. The immediate change in the whole well-being of such children after operation is wonderful.

Great care should be taken of children after the operation. Although it may be hard to follow the practice of Butlin and keep them in bed for a week, they can at least be kept in the house. Not only is the sudden communication of the middle ear with the out-door air liable to cause trouble, but the loss of so much blood is said to increase the liability to bronchitis and pneumonia.

Dr. KNAPP, who was present by invitation, said that he had been much interested in the result of Dr. Hooper's operations. He had seen adenoid vegetations a year ago in a patient who had cerebral infantile paralysis of an unusual type, — not the ordinary form of paralysis with rigidity and contraction, but a partial paralysis with intermittent spasm, ataxia, and associated movements. The combination of the paralysis with the peculiar expression caused by the adenoid growths — the half-open mouth, the dropped and protruding lower jaw, the half-articulate speech, the vacant expression, and the constant drooling — led to the thought of idioey, but he was surprised to find that the child was bright and intelligent. The parents were anxious to have something done for the drooling, even if nothing could be done for the paralysis. Thinking that the drooling might be caused by some trouble in the nose or naso-pharynx, he sent the child to Dr. Hooper, who found a mass of adenoid vegetations, which were removed. On seeing the child a month or two later, he was struck with the change in her appearance, from an apparent idiot she became a bright and attractive child. Some time after he saw a second case of cerebral infantile paralysis, with the

¹ See page 261 of this number of the Journal.

² See page 268 of this number of the Journal.

same symptom complex, only less severe, where there was also drooling and mouth-breathing. This child suffered from frequent colds, which were doubtless induced or aggravated by the fact that the constant drooling kept the clothing over the front of the chest constantly wet. Dr. Hooper operated on this child, and the speaker had seen him a month ago greatly improved. A third case, on which he had seen Dr. Hooper operate was an idiot. He believed that adenoid growths were often the cause of the drooling seen in idiots, and he thought that operation might relieve a very unpleasant and repulsive symptom. He had been struck with the co-existence of this condition with the rare form of paralysis. Certain deformities of the bony structure of the nasal and oral cavities, notably the high narrow palate, are not uncommon in cases of arrested cerebral development, either secondary to it, or a cause of it, from premature ossification of the sutures; might it not be possible that there was also some connection between these growths and the arrested development?

Dr. DEBLOIS spoke of the atrophy of these growths in adult life, and alluded to cases in his practice where the extreme toughness of the vegetations rendered their removal impossible.

Dr. F. B. HARRINGTON said that the slight difficulty arising from bleeding was at first a surprise to him, but in the number of cases that had come under his observation he had never seen any trouble, the blood readily flowing down the œsophagus.

Dr. E. M. BUCKINGHAM read a paper upon

NOCTURNAL INCONTINENCE OF URINE.*

Dr. FOLSON had seen a number of cases of incontinence of urine in children, and had rarely failed of success in their treatment with electricity used persistently, and of as strong a current (faradic) as the child could comfortably bear. In a few cases, circumcision is also required. These children are chiefly neurotic or of neurotic families and for the most part sound sleepers. In some of them the neuropathic element is so strong that they never fully learn to control their bladders except as they grow older; in the mean time they must be awakened at night at gradually lengthening intervals.

Dr. F. C. SHATTUCK had in one case failed with the induced current, one pole in the rectum, the other on the perineum, and afterwards attained a large increase of success with belladonna and nux vomica.

Some years ago he had been called to advise a lady who for seventeen years had been unable to hold her water for more than an hour at a time, a source of very great inconvenience to her. She had been treated by one physician without benefit. She was of a gouty family and had also some symptoms of that disease. The diet was regulated, and moderate doses of belladonna and nux vomica combined effected a complete cure, belladonna alone having failed.

Dr. A. H. NICHOLS has found all medicinal treatment of *incontinentia urinæ* as a rule unsatisfactory, owing to the obscurity with which the cause of the disorder is apt to be surrounded. Where, however, the trouble is of mechanical or reflex origin, such as is furnished by intestinal parasites, prompt relief may at times be afforded. A rare instance of this kind was related where a boy, having been ineffectually treated for a long period, was taken, on account of

certain nasal symptoms, to Dr. Langmaid. This gentleman removed from the posterior nasal cavity a calculus, the nucleus of which was formed by a boot-button which, it was then remembered, had been pushed within the nose some eight years previously. This operation was followed by an immediate and permanent cure of the incontinence.

Dr. J. S. GREENE reported a case of

ANEURISM OF THE ARCH OF THE AORTA.

The patient was a man, fifty-two years of age, a barber, of temperate and quiet habits. It is told that he used occasionally to have a wrestling struggle for fun with a man much younger than himself. Two-and-a-half years ago he began to be wheezy and to expectorate much mucus. Two years ago his voice began to be perceptibly husky, and after a few months he seldom spoke louder than a hoarse whisper. Two years ago, also, he had a sudden seizure of muscular lameness about the right shoulder which was promptly relieved by faradization: but thence forward he had frequently recurring stitches in the back and gradually a settled pain, which persisted during life at a point between the lower angle of the left scapula and the vertebral column. Decubitus was early limited to the left side. It became very hard and wearisome to keep his arms lifted at his work, and he was obliged to sit and rest after serving each customer. In the spring of 1887, he had to give up work. With some improvement in strength, he resumed for awhile in the autumn, but was unable to do much. Cough was a capricious symptom, being sometimes present to an annoying degree for weeks together, and then absent for a time. Late in November last he was suddenly seized at his shop after coughing, with urgent and alarming dyspnoea, accompanied by lividity, pallor and a thready pulse. After rallying from this condition under the influence of a quarter-grain dose of morphia used subcutaneously, he was conveyed home and there remained until his death, two days ago. During December, he had several similar attacks of dyspnoea without other apparent provocation than a slight cough, and always relieved by morphia. During the last five or six weeks of life, while exempt from these seizures, the mucus expectorated was daily more or less tinged with blood.

During the period of his final confinement to the house, he sat by day most of the time or wearily reclined towards the left, but at night could lie in bed without much orthopnoea. In the last two weeks of life, he had two or three choking fits with pallor, faintness, coldness and failing pulse, and in such a one he quietly died in his chair. The physical signs during his illness were a small pulse, without inequality at the two wrists: a heart with its apex-beat distinct and of about normal force, at the middle axillary line about level with the nipple; and a systolic impulse not strongly heaving but uniformly diffused over the whole left front, and extending at least an inch to the right of the sternum; marked venous turgidity at the neck; apparent pushing outwards of the upper part of the sternum; and bulging of the tissues at the base of the neck in front. There were never discovered any cardiac or other murmurs, nor abnormal chest-sounds of any kind, and there was never hæmorrhage more than the late bloody expectoration above mentioned. On this total of symptoms and signs, positive and negative, a clearly satisfactory diagnosis was not made:

* See page 270 of the Journal.

but an aneurism dislocating the heart toward the left was regarded as the most probable condition.

Dr. R. H. Fitz showed the aneurism.

The aneurism is fusiform, of the transverse portion of the arch, and is of the size of the head of a newborn child. The large branches of the arch arise from the anterior portion of the sac, near the middle, and are flattened but patent. The left pneumo-gastric nerve becomes lost in the wall of the aneurism.

The interna of the pulmonary artery, between the heart and the aneurism is separated from the middle coat over a distance of nearly two inches from immediately above the valves. Between the two coats is a dark-red thrombus of sufficient thickness to diminish the calibre of the cavity of the artery more than one-half. A probe passed beneath the detached interna at the upper end, enters the cavity of the aortic aneurism.

In the anterior wall of the trachea, about an inch above the bifurcation, is a nipple-shaped prominence in the centre of which is an opening permitting the passage of a probe into the aneurismal sac. A minute opening is also seen in the œsophageal wall through which a probe is passed directly into the aneurism. The left primary bronchus is flattened to a moderate extent. The corresponding lung is aerated, with the exception of a considerable portion of the lower lobe, which is collapsed and of a purple color.

The wall of the aneurism is thin and fibrous and is lined with a laminated, translucent, reddish-gray thrombus, in places nearly two inches thick. A less firm, darker thrombus, with an irregularly lobulated and ridged surface, is adherent to the older thrombus, and surrounds the canal for the passage of blood, which is large enough to admit the closed fist. The thrombus obstructs, though not completely, the orifices of the primary branches of the arch. The portions of aorta attached to the aneurism are dilated and elongated, the wall thickened, the interna wrinkled and opaque.

There is no enlargement of the cavities of the heart with the exception of a moderate dilatation of the right ventricle. The valves and muscular substance present no abnormal appearances.

THE NEW YORK ACADEMY OF MEDICINE.

STATED MEETING, February 16, 1888.

Dr. A. SEIBERT read a paper on

CHOLERA INFANTUM AND THE WEATHER.

Under the term cholera infantum, he explained that he included all cases of acute gastro-intestinal catarrh in children under five years of age. The paper was based upon observations made during a period of ten years, extending from January, 1878, to January, 1888, in the children's department of the German Dispensary, and was illustrated by a large number of charts. In a similar manner, he said, he had endeavored to point out the relation of the weather to fibrous pneumonia in a paper which he had published in the *American Journal of the Medical Sciences* in 1882.

The total number of cases of acute gastro-intestinal catarrh treated at the Dispensary during the ten years referred to was 8,036. As was naturally to be expected, the largest proportion of cases occurred dur-

ing the summer months, and the smallest number in the winter months. Thus, in the ten Julys there were 2,443 cases, and in the ten Augusts 1,524 cases; while in the ten Februarys there were only 117 cases. The monthly averages, however, were simply guides in the present inquiry, and it was not enough to take these alone. His statistics, as well as those of the Health Department, showed that the disease existed all the year round, even in the coldest weather, and that the proportionate mortality was just the same in cold as in hot weather — about one case in every four proving fatal.

It was a somewhat remarkable fact, the number of cases and deaths was always much greater in the month of July than in August. Thus, during the ten years the number of deaths reported in the city of New York in the month of July amounted to 12,428, and those in August to only 6,205. In July, 1881, when the mean temperature was 80°, the number of cases treated in the Dispensary was 290; in August of the same year, when the mean temperature was 82°, the number of cases was 223; and in September, when the mean temperature was 87°, the number of cases was 137.

During the summer months, it was found that the number of cases and of deaths bore no relation whatever to the rise and fall of temperature, and the same was true as regards the range of humidity; so that warm, moist weather did not predispose more to the disease than warm, dry weather. Dr. Seibert said that he had also made a very thorough investigation of the effect of light and heavy rain-fall, but totally without result. Previous to this it had been a favorite idea with him that want of water on the upper floors of tenement-houses was a somewhat important factor in the causation of summer complaint in the city. Local rain-fall also had no effect, and the same was true in regard to the velocity of the air-current.

Six years ago, he said, he had first pointed out the necessity of careful study of details, rather than of general averages, in connection with such subjects as this. As yet it was a disputed point whether direct heat was capable of causing the disease in question, and he had made a special study of all the hot days in the ten summers (when the thermometer reached 85° or higher). According to prevalent opinion, the months containing the greatest number of hot days ought to have had the greatest number of cases and of deaths; but he had found no evidence supporting this idea. Thus, in the last two weeks of June, 1880, there was a large proportion of these hot days, and in the same period of 1887 there were but few of them; yet the number of cases was just about the same in both of the fortnights mentioned. Again, in July, 1881, when there were but few hot days, there were 290 cases; while in July, 1887, which was considerably hotter, there were only 196, a ratio of 3 to 2. In July, 1884, the temperature never reached 90°, there were only three days when it went above 85°, and but eight days when it went above 80°. Yet there were 266 cases; while in August of the same year, which was a much hotter month, there were only 156 cases, or about one-third less. The difference in the mortality in the city during the two months was even more striking; the number of deaths being 1,109 in July, and only 633 in August. Yet this July was made up for the most part of what is usually regarded as very healthy weather; there

-being little excess of heat, frequent showery days, and many days with strong westerly breezes.

How, then, were we to account for the fact that in the warm months there are always such a large number of cases? It was evident, from the facts just pointed out, that *hot* weather was not necessary for the production of the disease. In regard to *warm* weather, however, the case was different; and the statistics collected showed that, in the early part of the summer season, as soon as the minimum daily temperature reached 60°, and this continued for a few days, an increase in the number of cases of acute gastro-intestinal catarrh was noticed. Furthermore, if the minimum daily temperature remained above 60° for a number of days (say for a week or more), it was noticed that the disease became epidemic; and this no matter how high above 60° the temperature might go, whether it was 75°, 80°, or 85°. These facts were found to be true in every one of the ten years which the statistics included. The reverse was noticed at the close of the warm season in October, the month of departure. During the first half of the month the minimum daily temperature usually reached 60°; but in the latter half, when the colder weather set in, the end of the epidemic occurred.

An examination of the records of every summer month, and of every day of each month during the ten years, had led him, thus, to the following conclusions:

First. Hot weather, either dry or moist, is not necessary for the epidemic appearance of acute gastro-intestinal catarrh.

Second. Warm weather, either dry or moist, showing a minimum daily temperature of not less than 60°, brings on the epidemic every year, irrespective of the height of the maximum daily temperature.

Third. The disease loses its epidemic character as soon as the minimum daily temperature falls below 60°, as in October.

Fourth. Therefore, this disease cannot be brought about by the direct effect of high temperature upon the child's body.

Dr. Seibert then went on to say that the lowest temperature of each day was reached during the night; and it was at this time that the milk which furnished the principal food of so many young children was brought into the city. It was often carried long distances, being much jolted about, and absorbing impurities from the time it left the cow. It was, therefore, only a question how far the decomposition of the milk had advanced by the time it reached the child. It was well known that a low temperature retarded decomposition, and Dr. Cyrus Edson, of the New York Health Department, had informed him that in his experience he had found that milk usually began to turn whenever its temperature reached 60° or higher. Chief Engineer Birdsall, of the Department of Public Works, had also informed him that whenever the temperature of Croton Lake rose to 60° or above, there was a peculiar taste about the water, which he attributed to the decomposition of certain matters contained within it.

As to the point why there are always so many more cases and deaths in July than in August, the difference usually amounting to at least one-third, it seemed to him that it might perhaps be explained by the fact that it took a few weeks after the onset of warm weather to fully arouse the tenement-house

population of the city to the danger to which their children were exposed from this disease, and to the necessity of taking suitable precautions as regards diet, fresh air, sanitary conditions, etc., for its prevention.

DISCUSSION.

Dr. L. EMMETT HOLT quoted some statistics published by a writer in Liverpool, which covered the five years ending with 1883 in that city. In one of these years the mortality amounted to 347 in July and 969 in August. The average temperature of July was 58.9, and of August 59.2; and this would seem to corroborate Dr. Seibert's statement concerning the increase of the disease when the temperature reached the neighborhood of 60°. In September, however, when the average temperature was only 55.9, there were 559 deaths; which, while much less than the mortality of August, was yet considerably greater than that of July. Still he thought that this might perhaps be explained by the fact, which he himself had noticed repeatedly, that a very hot August was apt to be followed by a high mortality in September, irrespective of the degree of heat in the latter month. Very much the same ratio as regards the different months was observed during the other years covered by the Liverpool statistics.

Dr. Holt then went on to say that in summer there were different forms of diarrheal disease in growing children, and that he thought it was advisable that some distinction should be made between them. In the production of what is ordinarily known as "summer complaint," he believed that there were four principal factors concerned; namely, (1) heat; (2) feeding; (3) sanitary conditions; and (4) constitution; and that the most important of these features was heat.

Dr. J. LEWIS SMITH said that he quite agreed with Dr. Holt in regard to the importance of distinguishing between the different forms of disease met with. He had seen cases in the warmest weather in which an aggravation of the symptoms resulted from reduction of temperature. The child took cold, and the disease was then apt to assume a dysenteric tendency. He thought there was perhaps a fallacy in comparing summer diarrhoea with the diarrhoea met with in cold weather, as he believed the latter to be an entirely different affection from the former. In the cooler months the causes of the trouble were usually so different that it was unjust to classify the two diseases together, although the lesions might be the same. The difference between the two was as great as that between the bronchitis incident to pertussis, or measles, and idiopathic bronchitis.

It seemed to him also that one might be misled by the number of deaths reported. Thus, many of the deaths occurring in August or September might be in children who had contracted the disease in the earlier part of the summer. The mortality, as a rule, was somewhat greater in September than in May, although the temperature was usually higher in the latter month than in the former; and the reason was because many of those dying in September had been taken ill in one of the previous months. He had noticed in his own statistics the difference between the mortality in August and that in September.

It could be stated in a general way, he thought, that the disease known as summer complaint is caused by heat; but in what way the heat operated to pro-

duce it was not as yet fully ascertained. It was evident that heat alone was not sufficient for its production, or else the disease would be found prevalent in the country as well as in the city. It must be a fact, therefore, that there were certain causes which were brought into operation by the insanitary conditions met with in the city in hot weather. How much gaseous exhalations had to do with the causation was not determined. At all events the opinion was gaining ground among the best observers that summer diarrhoea is a microbial disease. It was well known that milk which had begun to decompose had a tendency to give rise to the affection. In Asiatic cholera the causative agency of Koch's bacillus had been pretty generally accepted, and it was believed that this microbe was received into the mouth and acted as a source of irritation to the intestines by its actual presence, and not by causing decomposition of food. In like manner it did not seem unreasonable to suppose that micro-organisms might act in the same way in some cases of summer diarrhoea.

Dr. A. CAILLE said that the investigation of Dr. Seibert had not only confirmed the general opinion that warm weather was an important factor in the causation of summer diarrhoea, but had also brought out a number of interesting new facts. In his opinion decomposing milk was the chief exciting cause of the trouble. While Dr. Seibert was on the whole no doubt right, it was his opinion that high temperature sometimes does have a pernicious effect upon the human body, and this serves to pave the way for some agency which will give rise to diarrhoeal trouble. It was a fact that children nursed at the breast or brought up upon some of the numerous infants' foods in the market, who never get cows' milk, will sometimes be attacked with serious gastro-intestinal disease if allowed to overload their stomachs in hot weather, while they will suffer but little, if at all, under the same circumstances in cold weather.

Two French physiologists had made some experiments by exposing animals to a continual temperature of 104°, and the phenomena which they observed to result from the exposure were: (1) increase of nervous excitability; (2) nervous depression, and (3) convulsions, coma and death; death resulting more speedily in a moist high temperature than in a dry high temperature. The same results had been noticed to be produced in children when the weather was very hot. It was his opinion, therefore, that while high temperature did not directly produce diarrhoea, it did have a pernicious effect upon the system, and under these circumstances any irritating substance would be likely to give rise to diarrhoea.

As regards the smaller number of cases of summer complaint, as well as of deaths from the disease, in August than in July, he thought that perhaps one reason for this was that a much larger number of children left the city in August than in July, while those which remained had the advantage of the numerous fresh air excursions then provided for the poor.

The President, Dr. A. JACOBI, said that there was a great difference in the cases observed. The larger number were of a simple catarrhal nature. In others, where the discharges were serious in character, there was a tendency to collapse. In such cases the lesions found in the intestines after death might be very slight, while several of the organs of the body might be found to be in an advanced stage of granular de-

generation. He believed that great heat would kill by its direct effect upon the nerves and upon the muscular system, including the tissue of the heart itself; the high temperature having the effect of coagulating the myosine of the muscles. Intense heat also had a certain influence on the surface of the body; causing an immense dilatation of the capillary bloodvessels. Insufficient nutrition, particularly of the brain, would result from this, and thus collapse would be brought about. These were the cases of true cholera-infantum, which generally terminated fatally, and which were liable to be met with in well-to-do families as well as among the very poor. The large majority of the cases met with, however, were of gastro-intestinal catarrh.

Dr. JACOBI said he had been much interested in the fact demonstrated by Dr. Seibert's investigations that 60° was the turning-point for this disease, and it was especially noteworthy in this connection that Dr. Edson had expressed the opinion that milk began to decompose, and Chief Engineer Birdsall the opinion that water began to be affected by decomposition, also at 60°. In conclusion, he made some remarks in regard to the importance of proper feeding.

STATE CARE OF THE PAUPER INSANE.

At the same meeting Dr. SAMUEL SEXTON presented a resolution endorsing the bill prepared by the State Charities Aid Association in regard to the care of the pauper insane in State hospitals, and recommending its enactment by the Legislature. In connection with it he submitted a circular recently issued by the Board of Managers of the State Charities Aid Association in which they urge the passage of the Act, and bring forward the following arguments in its support. Those members of the Association who are as familiar with the management of the State Asylum, as they are with that of county poor-houses, find themselves obliged to acknowledge, in accordance with universal testimony, that, notwithstanding the fact that the condition of the insane in the latter is much improved, as compared with what it was not many years ago, the care furnished the insane by the State is vastly superior to that furnished by the counties. They know, also, that the counties do not propose to give the same character of care to their pauper insane, as that given by a State hospital, with its staff of alienist physicians always in attendance, its schools for training nurses, its large force of attendants, its various organized systems for occupation, instruction and amusement. This is impossible of attainment for any county at a weekly cost *per capita* of \$1.50. The expense of new or improved county buildings, and of a larger number and higher grade of attendants, which an advanced and enlightened public opinion now demands for the care of the insane, these two conditions alone — irrespective of maintenance and medical treatment — will impose a heavier burden on the tax-payer of the county than the additional increase of his State tax required to perfect the system already established by the State.

In concluding Dr. Sexton's resolution, Dr. C. R. AGNEW said that for thirty years he had been interested, with others, in the amelioration of the condition of the pauper insane in the State of New York, and that the first result of the agitation of this subject had been the establishment by the State, of the admirable Willard Asylum. Later, those at Binghamton

and Poughkeepsie had been started. The opening of these institutions had withdrawn a considerable portion of the pauper insane from the county poor-houses. Now, however, an effort was being made to establish local asylums for the insane in various counties. The chief reasons alleged for this movement were the saving to a considerable extent, of the cost of the transportation of insane patients and because it was claimed that the cost of maintenance in the State hospitals was unnecessarily great. One of the counties declared its willingness to undertake the care of its insane at a cost not to exceed 97 cents per head per week, and another for \$1.19. At the Willard Asylum, where the number of inmates was nearly two thousand, the expenses could not be reduced below \$2.25 per head per week; but this included the best scientific care by expert physicians and specially trained nurses, the amusement and intellectual training of the patients, and their employment in the workshop and on the farm connected with the institution. It was a fact also, that some of the counties had tried the experiment of having their own insane asylums, and unsuccessfully. Thus, Rockland County had erected one at an expenditure of \$20,000, and it had now been abandoned. If the pauper insane were cared for by the counties they would be under the charge of the supervisors and superintendents of the poor, and these men, besides knowing nothing about the proper care of the insane, were altogether too close to the tax-payers. This class of cases could, in fact, only be properly taken care of in an institution where there was a board of managers, which was directly responsible to the State, and where everything was done in the full blaze of public scrutiny; and in the State hospitals he believed that the most enlightened modern treatment of the insane was carried out in as thorough a manner as was at present attainable.

The resolution was then unanimously adopted.

Recent Literature.

Transactions of the American Surgical Association, Vol. V: By J. EWING MEARS, M.D., 1887. P. Blakiston, Son & Co., Philadelphia. pp. 386. Illustrated.

The above report, with the exception of the first few pages, on which appear a list of the officers and members of the association with the president's address, consists almost entirely of a reprint in full of the papers read before the association at its meeting held May 11, 12, 13, 14, 1887, with the ensuing discussion by the association. The recent numerous reports and criticisms in all the principal medical journals have so familiarized the profession with the character of these monographs as to render a detailed review superfluous. It is exceedingly gratifying to find the original articles thus reproduced in a form so convenient and readily accessible as in the neat volume containing this report, which will for many years furnish much valuable information to those surgeons interested in the important subjects thus so fully presented by their respective writers. Of especial interest at the present time are the articles entitled "Suprapubic Cystotomy," and "Gunshot wounds of the Abdomen," to which 218 of 377 pages are devoted.

The Principles of Theoretical Chemistry, with special reference to the Constitution of Chemical Compounds: By IRA REMSEN, Professor of Chemistry in the Johns Hopkins University. Third addition, enlarged and thoroughly revised. Philadelphia: Lea Brothers & Co. 1887.

The demand for a third edition of a work of this character is perhaps the best evidence of the favor with which Professor Remsen's book has been received. In the present edition, the chapter on valence has been almost entirely re-written and at the same time enlarged, chapters on chemical affinity, and the connection between constitution and chemical conduct have been added, and other additions have been made here and there throughout the book.

We can recommend this book as containing a reliable and connected account of the theories of chemistry which prevail at the present time.

Medical Lectures and Essays. By GEORGE JOHNSON, M.D., F.R.C.P., etc. London: J. & A. Churchill. 1887.

This octavo volume of nine hundred pages is for the most part a reprint of papers, which have been published in various forms and at different times during the last thirty years or more, with the advantage of careful revision. In their present form, therefore, these papers are endorsed by the author as his latest and most matured opinions upon the subjects of which they treat.

The latest work of the emeritus professor of clinical medicine at King's College, London, in regard to the physiology of the circulation, the influence of the contractile power of the muscular-walled arterioles upon the circulation and its relation to renal and cardiac disease,—a subject with which his name is identified,—will be read with careful attention. The physiological functions of the arterioles is dwelt upon in several chapters of the present volume.

The book consists of fifty chapters upon an almost equal number of subjects in Clinical Medicine, but the question of "Bright's Disease" alone takes up one hundred and fifty pages, and here the author's well-known views are developed at length.

Practical Urine Testing: A guide to office and bedside urine analysis. By CHARLES GODWIN JENNINGS, M.D., Professor of Chemistry and of Diseases of Children, Detroit College of Medicine, etc. Detroit: D. O. Haynes & Co. 1887.

The object of this book is explained by the following statements of the author:

"It is the aim of this little volume to give concise directions for office and bedside testing. Particular attention has been given to the qualitative and quantitative tests, which from their cleanliness and ease of application, and the simplicity of apparatus required, commend themselves to the practising physician."

A number of books of similar character have been published. One or two of these are excellent, and we do not believe there is any real necessity for another at the present time. However, the book which Dr. Jennings has added to the list is a very good one, and we can recommend it to those desirous of such a work, as one likely to meet their requirements. Most of the new urine tests that have proved to be of value may be found in this volume.

W. B. H.

THE BOSTON
Medical and Surgical Journal.

THURSDAY, MARCH 15, 1888.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States and Canada; \$6.00 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 94 Boylston Street.

All letters containing business communications, or referring to the publication, subscription or advertising department of this journal, should be addressed to the "Manager of the Business Department," Medical and Surgical Journal, 94 Boylston Street.

Remittances should be made by money-order, draft, or registered letter, payable to

CUPPLES AND HURD,
94 BOYLSTON STREET, BOSTON, MASS.

THE DETTWEILER METHOD OF TREATING
PULMONARY CONSUMPTION.

DR. PAUL H. KRETZSCHMAR has published in the *New York Medical Journal* an appeal for the establishment in this country of an institution (or institutions) for the rational treatment of pulmonary consumption after the model of Dr. P. Dettweiler's sanitarium at Falkenstein.

From the paper referred to¹ we ascertain the following particulars respecting the Dettweiler method of treatment:

The sanitarium in Falkenstein was founded in 1874 by a stock company, the shareholders not to receive more than five per cent. dividend on their investment, the surplus income to be used for the improvement of the institution. It is situated on the northern slope of the Tannas Mountains, about fourteen hundred feet above the sea-level near Cronberg, and two hours' ride from Frankfurt. It consists of three large buildings, together with gas-works, cow-stables, laundry, etc. The largest of the buildings presents the form of a horse-shoe, to protect the inhabitants from the rather heavy north winds which prevail there occasionally, and contains eighty rooms, with over one hundred beds, and the post and telegraphic offices, parlors, reading rooms, billiard room, offices, examination room, and the douche in the basement. The next building, connected with the others by an arcade, contains the large, high, and well-ventilated dining-room, which seats about two hundred people comfortably, the kitchen being outside of the building. The third building contains the residences of the medical superintendent and his associates.

The climate of Falkenstein is not alleged to have any specific influence on the diseased organs; it does not differ in any essential respect from that of Southern Germany in general, except that during July and August the temperature is quite high. The air is comparatively free from dust and other impurities. Well-cultivated pine and oak forests are in the immediate

neighborhood, with numerous attractive walks scattered through them, and with plenty of seats and places for rest. One of the points which Dettweiler considers as of the greatest importance in obtaining favorable results is *the treatment of phthisical patients within institutions* where they are constantly under the personal supervision of the attending physician. The medical profession of Germany approve of this view, and the institutions established in Germany on this basis have already made a good showing. In Goerbersdorf is the model sanitarium of Dr. H. Bremers, and two others have lately been established; even Falkenstein has a second one. Dr. Driver, of Reiboltsgrün, in Saxony, and Dr. Jacobasch, in the Hartz Mountains, are proclaiming good results in their respective places. In these institutions the smallest details of the patient's life are controlled by the supervising physician: the daily exercise in the open air, the use of lung gymnastics, the administration of stimulants, even the changing of garments, are matters not left to the judgment of the patients.

In connection with other phthisco-therapeutics, Dettweiler praises the invigorating influence of pure mountain air, and its great value as a remedial agent in the treatment of consumption, but to the patients boarding in his institution, he insists on the necessity of caution in outdoor exercise. New patients are not permitted to walk outside the immediate vicinity, or even remain outdoors a long time, until after the first careful examination, which is generally made by two physicians the day after arrival; the limit of outdoor exercise is then agreed upon; also the hours of rest in the open air, and the first instruction in lung gymnastics is given. Under ordinary conditions, the duration of outdoor living is increased daily, and the greatest importance is placed in "resting" in the open air. Over ninety *chaises-longues* — lounges made of rattan and upholstered with horse-hair — are placed over the verandas, the arcade, and the rotating pavilions, and the patients, after being acclimated, spend many hours daily, dressed properly, and covered with blankets, in accordance with the season, lying upon them. Dettweiler places great importance on this permanent air treatment, which is carried out even in cold weather, when snow and ice cover the surrounding ground. During the winter before last, which was an exceptionally cold one, a daily record was kept, and it was found that some of the convalescing and more energetic patients extended the so-called "*jour medical*" to ten and eleven hours; many of those that were advanced cases spent, at least, two or three hours on their rattan lounges. Only in exceptional cases — in highly anæmic subjects and those suffering from continuous and decided fever, with frequent chills — is the permanent air treatment not indicated. Six hours is the average time spent on the lounges; many remain there till ten o'clock at night, passing the time reading or writing, playing dominoes or chess, the verandas and pavilions being well lighted after dark.

¹ *New York Medical Journal*, February 18, 1888.

Another feature of the treatment, supposed to strengthen the system and harden it against unfavorable external influences, is the systematic use of massage and the regular rubbing down of patients, early in the morning and before rising, by trained nurses, first by means of dry towels, afterwards with alcohol, and occasionally with salt water. The cold douche is added in most cases to other invigorating measures.

Much attention is paid to diet. Dettweiler considers anorexia, next to pyrexia, the most important factor in destroying the life of phthisical patients. All the delicacies of the season are provided, and much attention is paid to the individual wants of each case. As a rule, the patients take their meals together, one physician being always with them, and the time for meals is thus arranged: First breakfast, consisting of coffee, tea, chocolate, or milk, with cakes or rolls, and butter and honey, from 7 to 8.30 A. M. Second breakfast: bread and butter, with milk, always as much as desired, or bouillon and cold meat, at 10 o'clock A. M. Dinner, the principal meal, consisting of soup, fish, or broiled meat roast, with a variety of vegetables, salad and compote, and dessert, at 1 P. M. With the dinner, each patient drinks from one-third to half a bottle of Rhine or Hungarian wine and a cup of coffee. At 4 o'clock P. M., an additional lunch to those that require it of fresh milk, and a nice little room is arranged for this purpose in the cow-stable. Lastly, a warm supper is provided of soup, warm and cold dishes, of meat, etc., at 7 P. M., with a glass of wine. Instructions are given to eat slowly and chew well; milk, especially, must be taken only a swallow at a time. The food is well prepared and cooked rather rich, and the manner of cooking is often changed. Dr. Dettweiler himself directs the management of the kitchen. He says that few of the patients do not enjoy the meals at Falkenstein, and 86 per cent. of all patients gain an average of nine pounds each during a period of less than three months, while 14 per cent. do not increase in weight. The free use of alcohol is also a feature of Dettweiler's treatment. Dettweiler says that he would give one-half of the entire *materia medica* for this one remedy. The phthisical patient with a fair appetite and free from fever does not require more than three-fourths to one bottle of good Rhine wine a day; if, however, anæmia be a prominent symptom, with occasional chills, he orders the "brandy treatment": two teaspoonfuls of pure brandy, to be taken every hour or two from morning till night, amounting to eighty grammes a day, to be followed by a brandy milk-punch before retiring.

The laws of hygiene are strictly enforced at Falkenstein: the patients sleep with their windows open during the night, pure water is at hand, the greatest cleanliness prevails, the drainage is the best, and cuspidors are at hand filled with a solution of bichloride of mercury, to receive the expectoration of the patients. The average attendance during the last years has been 160 in the summer, and 120 in the

winter. The expenses, including wine, milk, douche, bath, and medical attendance, amount to not over twelve marks, or three dollars a day. Dr. Dettweiler has lately published a pamphlet relating to the permanent cure of seventy-two cases of pulmonary consumption by his "permanent air and rest treatment," with the administration of such a liberal and rich diet as to amount almost to over-feeding.

Dr. Kretzschmar, from whose interesting communication we have derived these particulars, pertinently asks: "Why should we not try the system in this country?" and calls for the establishment of sanatoria of the same kind in New York and New England.

The question naturally arises in this connection: Would such an institution in New England prove at once useful and self-supporting? It must be borne in mind that in this country consumption prevails largely among the poorer classes, few of whom could find three dollars a day for board and medical attendance.

THE FIRST CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS.

THE Executive Committee of the Congress of American Physicians and Surgeons has issued its preliminary programme for the first Congress, which it is proposed should be held in Washington on the evenings of September 18th, 19th, and 20th. All the special national societies and associations which have been approached on the subject have agreed to participate in the Congress, with the exception of the American Gynecological Society.

Surgeon John S. Billings, of Washington, has been chosen President of the Congress, and the various Presidents of the participating societies are *ex-officio* Vice-Presidents. Dr. William Pepper, of Philadelphia, is Chairman of the Executive Committee, and Dr. William H. Carnalt, of New Haven, is Secretary.

The daytime will be reserved for the usual work of the component organizations, whilst the evening hours only of the three days, it is proposed, shall be given to the exercises of the Congress as a body.

The subject assigned for the first evening, Tuesday, September 18th, is the important one of "Intestinal Obstruction," which will be considered in its medical and surgical relations; papers viewing it from these points of view respectively will be read by Dr. R. H. Fitz, of Boston, and Dr. Nicholas Senn, of Milwaukee, and a discussion will follow. The next evening, "Cerebral Localization in its Practical Relations" will be treated by Drs. Charles K. Mills, of Philadelphia, and Roswell Park, of Buffalo, and then discussed by the Congress. The third evening, Thursday, will be occupied by an address by the President, Dr. Billings, and by a subsequent general reception in the new United States Army Museum Building.

The occasion can hardly fail to prove one of much interest and improvement for those in attendance, who will probably include some distinguished members of the profession from the other side of the At-

lantic. The Congress means work, and no entertainments or distractions are provided for, other than the Reception above referred to at the end of the last day; in fact, for those who come with a serious purpose — and there will probably be no others — of attending the regular work of their special societies and of the Congress, there will be no time for other things.

We do not doubt that the impression made by this first Congress will be such as to establish the proposed triennial assemblages upon a firm and lasting basis.

ANNUAL REPORT OF THE TRUSTEES OF THE MASSACHUSETTS GENERAL HOSPITAL AND McLEAN ASYLUM.

The report of the trustees of the Massachusetts General Hospital for the year 1887, the seventy-fourth annual report, (which includes reports of the treasurer, of the resident physician of the Hospital, Dr. J. W. Pratt, and of the medical superintendent of the McLean Asylum for the Insane, Dr. Edward Cowles,) presents information upon the usual subjects.

Dr. Francis Minot resigned his position as visiting physician after twenty-eight years of valuable service. The office of aural surgeon was created, and Dr. J. Orne Green chosen its first incumbent.

The whole number of patients received at the Hospital in the course of the year has been 2,814 — 1,539 men, 1,083 women, and 192 children, of whom 36 were under two years of age. For the year 1886 it was 2,580 — 1,442 men, 948 women, and 190 children, 21 of whom were under the age of two. The average number of patients in the Hospital has been this year 185, of whom, on the average, 161 had free beds. Last year, the average number of patients was 173, with an average of 152 free beds. The Convalescent Home received 327 patients.

The number of surgical patients, as usual, considerably exceeded the number of medical. Of the former there were 1,674, and of the latter, 1,140. The number of patients received on account of accidents was 490. Of the total number of patients, 1,376 were American born, and 1,438 were foreign born. Fourteen per cent. of the free patients were female domestics; seventeen per cent. were laborers; thirteen per cent. were mechanics; and nine per cent. were minors.

The average time of paying patients was 2.90 weeks, and that of free patients 3.57 weeks. The proportion of deaths to the whole number of results was 8.78 per cent.

The total expenses for the Hospital were \$120,881.61 of which \$105,543.71 was on account of free patients and \$15,337.90 on account of paying patients. The average cost per week per capita in 1886 was \$12.50 and in 1887, \$12.56.

The receipts at the Convalescent Home exceeded the expenses \$809.39; the expenses at the Hospital exceeded the receipts \$18,772.14; the expenses at the McLean Asylum exceeded the receipts \$5,019.34; the net deficit for the year was \$22,982.09. It is

evident from these constantly recurring annual deficits, that the hospital must either secure increased funds for the support of free beds, accept fewer free patients or continue to encroach upon the principal of the general funds of the Hospital applicable to its yearly expenses.

The bequests and donations received during the year amounted to \$37,873, in comparison with \$70,403.71 received the preceding year.

At the McLean Asylum the whole number of cases within the year was 242 — representing 237 persons — of whom 78 were discharged within the year. The daily average number of patients was 160.24.

Of the seventy-four persons admitted during the year, thirty-nine were regarded as recent cases, and thirty-five as chronic, or incurable. Fifty-four persons, twenty-one men and thirty-three women, had never been in any hospital. Of the remaining twenty persons, fifteen, seven men and eight women, were admitted for the second time; three persons, two men and one woman, for the third time; one woman for the fourth time; and one man for the twenty-third time.

Thirty cases — representing twenty-nine persons, fourteen men and fifteen women — were admitted as voluntary patients upon their own written applications. Of these, seventeen were cases of melancholia, seven of mania, one of hysteria, and four of general paralysis. Of these twenty-nine persons, two were committed after entering the asylum as voluntary cases, and one was twice admitted as a voluntary case. The thirty voluntary cases admitted during the year furnished eight recoveries; and twenty-five such cases remaining from previous years furnished five other recoveries during this year, making a total of thirteen recoveries out of fifty-five cases, — the total number of this class under treatment during the year. Thus, the voluntary class has yielded a percentage of 36.66 on the admissions of 1887. Of this class admitted during the year, four other cases were discharged improved or much improved, and four not improved. Of these thirty cases admitted in 1887 there were remaining, at the end of the year, fourteen persons, seven men and seven women; and thirteen persons, six men and seven women, also remained from the admissions of previous years, so that the total remaining under the voluntary relation is twenty-seven persons, thirteen men and fourteen women. The number of persons admitted as voluntary patients under the present law is as follows: namely, 1881, 1; 1882, 11; 1883, 33; 1884, 49; 1885, 34; 1886, 29; 1887, 29, — a total of 186 persons in seven years.

Of the seventy-six persons discharged, including deaths, seven, three men and four women, were transferred to other hospitals in this State. Of the twenty-five persons discharged recovered, eighteen had never before been inmates of any hospital; and all of the remaining seven persons had been in this Asylum.

These seven persons had previously made thirty-five recoveries.

The average duration of illness from the beginning of attack in all cases recovered, was 10.34 months, and the average duration of their residence in the Asylum was 6.86 months.

The percentage of recoveries on all admissions, for the year 1887, was 34.7. There were ten less recoveries than in the previous year. There were seventeen deaths, three more than last year.

The introduction and development of a training school for nurses has continued to give satisfactory and gratifying results.

THE BEST METHOD FOR THE EXECUTION OF CRIMINALS.

At its last meeting, held March 8th, the Society of Medical Jurisprudence and State Medicine of New York discussed the best method of executing criminals. Dr. William A. Hammond, who opened and closed the discussion, advocated strangulation by a silk or cotton rope as the most satisfactory method at command. He criticised the recent report of the State Commission, which recommended the use of electricity, and said that the objections raised against the present method of execution would apply with equal force to any form of execution. Several of the members took exception to Dr. Hammond's statement that strangulation was painless, and Drs. Spitzka and Brill spoke in favor of the guillotine.

The Society finally adopted, by a nearly unanimous vote, a resolution condemning the bill now before the Legislature, which embodies the recommendations of the State Commission referred to.

MEDICAL NOTES.

BOSTON AND NEW ENGLAND.

— A large number of members of the City Government visited the Boston City Hospital in an official capacity last week.

— Dr. Alexander Fulton, an aged and popular physician of Ellsworth, Me., died recently.

— Ellen Murphy, sixteen years old, living at No. 16 Berlin St., Roxbury, availed herself of the short and easy means to suicide provided (we had almost said — it is, at least, permitted) by the State laws, and took a dose of "Rough on Rats" at 1.15 o'clock one morning last week. She was removed to the City Hospital, where she died at six o'clock.

— Dr. C. A. Lovejoy, Superintendent of the Lynn City Hospital, reports the number of patients admitted during the year at 260; in the Hospital December 1, 1886, 11; total number treated, 271. Of the 255 discharged, 163 were well, 52 relieved, 11 not relieved, and 29 died; expenses, \$8,639, an average of \$40 per annum, or \$3.56 week for each patient. The average cost for each admission to the Hospital has been \$32.18. While the number of patients the

past year has materially increased, the accounts show that the expenses have been considerably less. For instance, the item for household expenses has been reduced from \$4,131, with an average of sixteen patients, to \$3,602, with an average of nineteen patients, or from a cost for fuel, light, and provisions of \$258 per head in 1886, to \$189 per head the past year.

NEW YORK.

— The forty-seventh annual commencement of the Medical Department of the University of the City of New York was held at the Metropolitan Opera House, March 7th, when the chancellor of the university, the Rev. Dr. John Hall, conferred the degree of M. D. upon one hundred and sixty-four candidates. The usual prizes were awarded, and the address to the graduating class was made by the Rev. William M. Taylor, D. D.

— The annual commencement of the Long Island College Hospital was held at the Brooklyn Academy of Music, March 9th, when the address to the graduates, who were thirty-six in number, was made by the Rev. Dr. T. deWitt Talmage.

— President Baylies, of the Board of Health, has just received the diploma awarded to the department for Designs for Sanitary Works by the International Health Exhibition, which was held in London in 1884. It is signed by the Prince of Wales, as president of the exhibition, and the Duke of Buckingham, as chairman of the executive committee.

— At the unveiling of the tablet in memory of Prof. Austin Flint, erected in the Carnegie Laboratory by the Alumni Association of Bellevue Hospital Medical College, which took place on the evening of March 10th, Dr. David Webster, President of the Association, presided, and opened the exercises, after which a eulogy of Dr. Flint was delivered by Dr. Leroy M. Yale. The tablet, which was accepted by the president of the College, Dr. Isaac E. Taylor, in behalf of the faculty and trustees, was executed by Alexander Doyle, of New York, and presents an excellent likeness of Dr. Flint in bronze.

— Dr. T. R. S. Drake, Professor of Clinical Medicine in the New York University Medical School, died, after a brief illness, on March 9th, in the forty-third year of his age. He was a native of Connecticut, and a graduate of Yale College. He studied medicine at the college where he afterwards became professor, and after receiving his degree served on the house-staff of Charity Hospital, Blackwells Island. On entering private practice he became the junior partner of Dr. Alfred L. Loomis, and during his association with the latter became attending physician first to Charity Hospital, and subsequently to Bellevue. He was distinguished for his skill as a diagnostician and the aptness which he showed as a clinical lecturer, while he greatly endeared himself to the students under his instruction. He was for a number of years president of the Alumni Association of the University Medical School, and recently was

vice-president of the Medical Society of the County of New York. In both the County and State Medical Societies, as well as the Pathological Society, he took a deep interest, and he was always very active in securing desired medical legislation at Albany. Generous to a fault, devoted to his friends, and with a warmly sympathetic and genial nature, he was beloved and esteemed by his patients and a wide social circle, and his untimely death is a most deplorable loss. Dr. Drake leaves a widow and two young children.

PHILADELPHIA.

— At the last meeting of the College of Physicians Dr. John Ashhurst, Jr., presented a patient about twenty years of age, upon whom he had successfully performed a synchronous triple amputation. As a result of being run over by a train on the railroad, the man had suffered the following injuries: crush of the right leg, which was lacerated above the knee; avulsion of the leg at lower third; crush of right hand and wrist; scalp lacerations, and compound fracture of the skull in frontal region, impacted; with laceration, followed by deep sloughing on buttock. He was immediately brought into the hospital of the University of Pennsylvania, which was near the scene of the accident, when his general condition was found to be very good; temperature, 99°. On the same day, November 28, 1887, primary synchronous amputation was performed of the three injured members: the right thigh by anterior and posterior flaps, using Es-march tubes to prevent hemorrhage; the left leg was amputated by a modification of Sédillot's method; and the right forearm was removed at the lower third. No irrigation was used. Antiseptic dressings were applied. The fracture of the skull and scalp laceration were treated as usual. At the conclusion of the operation the patient's temperature was 98°. The reporter particularly insisted upon the danger of allowing the patient's temperature to be lowered by exposure of the body during operation, and for this reason deprecated the use of wet towels and irrigation as ordinarily used in antiseptic surgery, and which often turn the scale against the patient. The man made a rapid recovery without any unfavorable symptoms. This is the only case on record of successful triple synchronous major amputation. He reported a second case in a man twenty-one years of age, in which both legs and the right forearm had been amputated for similar injury, but which had proved fatal on the tenth day, death being due to alcoholism. Out of fifteen double synchronous amputations he reported five recoveries, with ten deaths. Of two triple synchronous amputations the one presented alone recovered.

— At the same meeting Dr. John B. Chapin read a paper entitled, "Report of Cases of Traumatic Tubercular and Syphilitic Insanity." Dr. H. C. Wood took exception to the term syphilitic insanity, since the insanity is due to lesions which may or may not be due to syphilis. He also doubted the propriety of

the use of melancholia as a term indicating a morbid state. He claimed that it was only a symptom, and was no more correct to call it a disease than a similar application of "d Dropsy" would be. Dr. Woodbury cited "morbid fear" as a condition accepted by alienists as indicating mental unsoundness, yet no gross lesions may exist to account for it; and cited syphilophobia as a form of mental disturbance which may become so severe as to lead to insanity and suicide. If a group is to be made of syphilitic insanity, possibly some such cases might find place therein.

— The Second Sanitary Convention, to be held under the auspices of the State Board of Health, has been postponed from May 8th and 9th to May 17th and 18th, as the earlier date was found to conflict with the time for the meeting of the American Medical Association. The convention will be held in Lewisburg, a pretty university town, five hours distant by rail from Philadelphia. Prominent sanitarians will be invited from all parts of the country, and attention will be directed to the good work done by our State Board of Health, in the hope that the legislature will appropriate sufficient funds to enable it to largely extend its usefulness.

— Dr. M. B. Musser, in early middle-life, died rather suddenly of Bright's disease, a few days ago. He was one of the obstetricians to the Philadelphia Hospital, and probably the most prominent and successful physician in the western part of the city, and was universally loved and respected. He was a member of many medical societies.

— Dr. O. H. Allis has commenced a course of free lectures to the profession on the Mütter foundation, at the College of Physicians, on the "Articulations." This is a subject to which the lecturer has devoted much study, and the results of his many years' observations and experience as a surgeon promise to make this course unusually interesting and valuable.

Correspondence.

COMMITTEE ON ETHICS AND DISCIPLINE OF THE MASSACHUSETTS MEDICAL SOCIETY AND THE MURDOCK LIQUID FOOD HOSPITAL.

Boston, March 12, 1888.

MR. EDITOR,—Owing to correspondence published in the JOURNAL of the 1st inst., the Committee on Ethics and Discipline desire to make the following statement:

Shortly before the Councilor's meeting in October, 1886, Dr. E. W. Cushing called upon three members of the Committee separately, and asked for a formal opinion as to the propriety of his accepting the position of surgeon to the Murdock Liquid Food Hospital. Each member declined to express an official opinion, but each stated his views. October 8, 1886, Dr. Cushing addressed a letter to the Chairman of the Committee stating his relations to the Hospital, but he did not request action by the Committee.

The Committee had never been asked to consider the subject, and they desire to say that if asked, they could not have done so without exceeding the powers delegated to them.

Very respectfully,
FRANCIS W. GOSS, M.D., Secretary.

PRELIMINARY PROGRAMME, THIRD ANNUAL MEETING OF ASSOCIATION OF AMERICAN PHYSICIANS.

The following is the preliminary programme of the Third Annual Meeting of the Association of American Physicians, to be held in Washington, D. C., on the mornings and afternoons of September 18, 19 and 20, 1888. The meeting will be held this year in September, instead of June as hitherto, on account of the assembling at that time of the first Congress of American Physicians and Surgeons.

President's Inaugural Address, William H. Draper, New York.
Discussions. The Relation between Tropic Lesions and Diseases of the Nervous System: *Referer*, Edward C. Seguin, New York; *Co-Referer*, William T. Councilman, Baltimore. The Absolute and Relative Value of the Presence of Albumin and Casts, and of Renal Inadequacy, in the Diagnosis and Prognosis of Diseases of the Kidney: *Referer*, Robert T. Edes, Washington; *Co-Referer*, Edward G. Janeway, New York.

Papers. The Cardiac Changes in Chronic Bright's Disease, Alfred L. Loomis, New York; The Relation between Chronic Interstitial Nephritis and Angina Pectoris, Samuel C. Chew, Baltimore; Diarrhoea of the Heart-Rhythm with Reference to their Causation and their Value in Diagnosis, Gustavus Baugarten, St. Louis; Fatty Heart, Frederick Forchheimer, Cincinnati; The Cardiac Lesions producing the Presystolic Murmur, Frank Donaldson, Baltimore; The Treatment of Val-

vular Affections of the Heart, Jacob M. DaCosta, Philadelphia; Clinical Investigation in the Treatment of Cardiac Disease, James K. Thacher, New Haven; Casual Therapeutics in the Infectious Diseases, James C. Wilson, Philadelphia; Management of the Stage of Convalescence in Typhoid Fever, James H. Hutchinson, Philadelphia; The Geographical Differences in Typhoid Fever in the United States, W. W. Johnston, Washington; The Pathology of the Thyroid Gland, Abraham Jacobi, New York; Gastric Neurasthenia, George M. Garland, Boston; Neuritis, Francis T. Miles, Baltimore; The New Cesarean Section, William T. Lusk, New York; Is Hysterio-Epilepsy Better Treated by Medical or Surgical Means? William L. Polk, New York; Subject not yet announced, Samuel C. Busey, Washington; Subject not yet announced, George Ross, Montreal.

Demonstration in Pathological Anatomy: T. Mitchell Prudden, New York; William H. Welch, Baltimore.

APPOINTMENT.

Members of the family of the late Dr. Samuel Cabot have offered the Massachusetts General Hospital a fund of \$10,000 to be known as The Samuel Cabot Fund, the income to be used as a salary for the Pathologist. The offer has been accepted by the trustees, and Dr. W. F. Whitney has been appointed under the provision with the title of Assistant Pathologist.

REPORTED MORTALITY FOR THE WEEK ENDING MARCH 3, 1888.

Deaths reported 2,300; under five years of age 806; principal infectious diseases (small-pox, measles, diphtheria and croup, diarrhoeal diseases, whooping-cough, erysipelas and fevers) 310, acute lung diseases 413, consumption 504, diphtheria and croup 105, scarlet fever 44, diarrhoeal diseases 30, typhoid fever 53, measles 26, cerebro-spinal meningitis 20, whooping-cough 16, puerperal fever 12, erysipelas 10, malarial fever three, small-pox one. From typhoid fever, Philadelphia 12, Boston four, New York, District of Columbia and Lowell three each, New Orleans and Pittsburgh two each, Baltimore, Lawrence, Springfield and Holyoke one each. From measles, Baltimore 13, District of Columbia eight, New York two, Philadelphia, Pittsburgh and Holyoke one each. From cerebro-spinal meningitis, New York six, Philadelphia, New Orleans, Milwaukee and

Lowell two each, Boston, Pittsburgh, Worcester, Fall River, Springfield and Somerville one each. From whooping-cough, Philadelphia five, New York four, Baltimore two, Boston, District of Columbia, Cambridge, Fall River and Lawrence one each. From puerperal fever, New York and Milwaukee three each, Baltimore, Boston, District of Columbia, Pittsburgh, Chelsea and Waltham one each. From erysipelas, New York and Philadelphia four, Boston and Newburyport one each. From malarial fever New Orleans three. From small-pox, New York one.

In 20 cities and greater towns of Massachusetts with an estimated population of 1,029,813, the total death-rate for the week was 24.59 against 24.03 and 23.20 for the previous two weeks.

The meteorological record for the week ending March 3, in Boston, was as follows, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

Week ending	Barom-eter.	Thermometer.		Relative Humidity.			Direction of Wind.		Velocity of Wind.			State of Weather. ¹			Rainfall.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM MARCH 3, 1888, TO MARCH 9, 1888.

FISHER, W. W., first lieutenant and assistant surgeon. Sick leave extended one month on surgeon's certificate of disability. S. O. 50, A. G. O., March 2, 1888.

SHILLOCK, PAUL, first lieutenant and assistant surgeon, recently appointed. Ordered for duty at Fort Assiniboine, Mont. S. O. 50, A. G. O., March 2, 1888.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE UNITED STATES NAVY DURING THE WEEK ENDING MARCH 10, 1888.

STONE, E. P., assistant surgeon. Detached from the Coast Survey Steamer "Bahe," and to Hospital, New York, for treatment.

KENEY, JAMES F., assistant surgeon. Commissioned March 1, 1888.

BRUSH, GEORGE R., surgeon. Ordered to the "Omaha" when "Pensacola" arrives at Aspinwall.

MEANS, VICTOR C. B., passed assistant surgeon. To the "Omaha" when "Pensacola" arrives at Aspinwall.

SOCIETY NOTICE.

MASSACHUSETTS MEDICAL SOCIETY. STUFFOLK DISTRICT.—The Section for Obstetrics and Gynecology, will meet at 19 Boylston Place, on Wednesday, March 21st, at 7.45 o'clock. Dr. J. W. Farlow will report a "Case of Suppression of Urine for Thirteen Days, from Compression of Both Ureters," with specimen. The discussion will be opened by Drs. A. T. Cabot, R. H. Fitz, W. W. Jammet, and E. S. Wood.

J. W. FARLOW, M.D., *Chairman*.

GEORGE HAYES, M.D., *Secretary*.

"The Pinckney."

RESIGNATION.

Dr. G. W. West has resigned his position as Surgeon to Out-patients at the Massachusetts General Hospital.

OBITUARY. DR. CHARLES B. WELLINGTON.

Dr. Charles B. Wellington died in Cambridge, Mass., (where he was born), February 17, 1888, aged twenty-eight years. He graduated at the Harvard Medical School in 1885. Not long afterward, at the opening of the New Cambridge Hospital, he was chosen the House Physician. After holding this office a year he resigned it, and became associated with his father, Dr. W. W. Wellington, in the general practice of his profession in Cambridgeport.

He was a young man of singular sweetness of character and unswerving professional promise, as will be seen from the following well-merited tribute paid to his memory by the Trustees of the Cambridge Hospital, who at a recent meeting of their Board:

Voted, That the Trustees have learned with much sorrow of the death of Dr. Charles B. Wellington, the first House Physician of the Hospital; and they wish to place on record the high

esteem in which they held him. They bear witness to his fidelity to the new duties which were assigned to him in the organization and administration of the Hospital; to the constancy of his service; to the carefulness and ability of his professional work; and to the uniform courtesy and thoughtfulness and heartiness which marked his personal and official life.

His name will be cherished by all who have been associated with him; who have valued his friendship, and will tenderly preserve the memory of his generous and helpful life.

The Trustees desire to extend to the family of Dr. Wellington their profound sympathy at the removal of one whose character and spirit rendered him peculiarly endeared, and whose life held so much promise of usefulness and honor in the profession which was his heritage and choice.

BOOKS AND PAMPHLETS RECEIVED.

The Cure of Ilium. By Henry O. Marey, A.M., M.D., of Boston, Mass. Reprint. 1887.

CASES OF OPEN INCISION IN WRY NECK, CONTRACTED KNEE AND TALIPES VARUS.¹

BY E. H. BRADFORD, M.D.,
Visiting Surgeon, Boston City and Children's Hospitals.

OPEN INCISION IN WRY NECK.

The ordinary method, as is well known, for operating in wry neck due to contraction of the sternal cleido-mastoid muscle is by subcutaneous tenotomy of the muscle. The advantage of the subcutaneous method may be stated to be as follows: the absence of scar; the lessened danger of suppuration. The disadvantages of tenotomy in this locality are: (1) the difficulty of dividing thoroughly all the fibres of the fasciæ; and (2) in case of imperfect division, it is difficult to thoroughly find the resistant point without incurring a danger with deeper incisions of dividing important vessels. The advantages of the open incisions are chiefly that the surgeon is thereby enabled to clearly view the resisting points. The disadvantages are those of scar and the danger of suppuration. The danger of suppuration can be entirely done away with by proper aseptic precautions. The danger of scar is very slight, provided there is no suppuration and a clean incision is made. Moreover, if the incision is made in the hollow above the clavicle, parallel to the clavicle, a linear scar will not be noticed. The great advantage of an open incision is the thoroughness of incision and the lessened time required for mechanical after-treatment. The two following cases will serve as illustrations:

CASE I. Boy, aged eleven, congenital, anterior torticollis; right sterno-mastoid prominent; slight lateral curvature of spine, with bony distortion of vertebrae. An open incision was made one inch and a half above the clavicle, reaching from the outer border of the clavicular insertion of the muscle to the inner border of the sternal insertion. Incision was made down to the platysma muscle, which was divided on a director. The outer fascia of the neck was divided also, and the belly of the muscle thoroughly divided on a director—first the clavicular, then the sternal branch. After thorough division, the finger was inserted into the wound and some contraction felt of the fascia beneath the muscle. This was easily seen by opening the wound by means of retractors and divided without difficulty. The skin was then sewn up with catgut, leaving catgut drainage, and septic dressing applied, operation having been done with antiseptic and aseptic precautions. The head was kept in the corrected position and the boy kept in bed for a week, after which the dressings were removed and the wound found entirely healed. No mechanical after-treatment was applied. Boy was seen six months later. There has been no re-contraction, the wry neck was almost entirely corrected, a slight distortion remaining, due to the twist in the spine and the osseous change in the vertebrae.

CASE II. Girl, fourteen years of age. Similar distortion of the right side. The right sterno-mastoid divided in the same way, healing up equally readily. A wire collar was applied, and is worn now by the patient, three months after operation, to correct, if possible, the slight distortion of the head secondary

to the twist in the spine, in the hope that this may diminish on the growth of the patient. In this, as in the preceding case, there was no contraction of the sternal cleido-mastoid muscle, the left. The scar in both these cases is hardly noticeable.

OPEN INCISION IN SPASTIC CONTRACTION OF THE KNEE-JOINT.

In cases of spastic paralysis or Little's disease, it has been shown by Rupperecht and others that a thorough and permanent cure of the contraction of the gastrocnemius muscle is possible by division of the tendo Achillis. It may be inferred, therefore, that perfect and thorough division of the ham-string muscles would also be beneficial in such cases, with contraction of the ham-string muscles causing a contraction at the knee. A thorough division of the ham-strings is, of course, possible by subcutaneous tenotomy, but a thorough subcutaneous division of the ham-string muscle is not always easy, and in the following case an open incision was done in the hopes of thorough correction.

CASE I. Boy eleven, with spastic paralysis of both legs. Walks about with both knees bent. Tenotomy had previously been performed on both tendons Achillis, thoroughly correcting the equinus, but no attempt had been made to correct the contraction at the knee-joint. With proper antiseptic precautions, the skin in the popliteal space was divided by a V-shaped incision, the apex pointing downwards, and the ends reaching beyond the hamstring tendons. The skin was dissected back, and the fibres of the faciæ divided by cross incisions as the limb was carefully straightened, the tendons of the ham-string being divided in the same way. After thorough division of all the faciæ and tendons the limb was straightened and the skin sewed together. A straight splint applied outside of aseptic dressings. The wound healed readily, and two weeks later the operation was repeated upon the other limb, which also did well. The patient was seen six months later, and there was no return of the deformity, but the patient's attitude was not materially improved, for the reason that there was found to be a spastic condition of the psoas and iliacus muscle, which, when the lower limb was straightened threw the trunk forward, making locomotion ungainly.

OPEN INCISION IN CLUB-FOOT.

Open incision in club-foot has been recommended by some surgeons, but in ordinary cases, when operative interference is necessary, a division of the skin is unnecessary. Tenotomy and division of the ligaments answer every purpose if followed by proper mechanical treatment.

In certain cases, however, of resistant club-foot the foot cannot be thoroughly corrected ordinary even by operative measures, after forcible mechanical correction following tenotomy, with complete division of the ligaments as has been advocated by Shattuck and Parker. In these resistant cases, marked distortion of the neck and head of the astragalus delays cure, and after thorough correction, the front of the foot readily slips back, so that the scaphoid should articulate with the distorted facet of the astragalus. In such cases open incision (which is simply a more extensive tenotomy) will not be thoroughly adequate. Treatment in these cases

¹ Read at a meeting of the Surgical Section of the Suffolk District Medical Society, January 4, 1883.

has been the application of a retention appliance after correction, (involving the thorough stretching or division of the contracted ligaments, fasciæ and tendons), until such time as is required for the formation of a new facet in the astragalus. Other treatment has been excision of the tarsus or removal of the astragalus. The former method of treatment is successful in a very large number of difficult cases. The latter method is also successful, and is without great danger, but both involve necessarily a considerable mutilation of the foot, which is to be avoided if possible.

The following method was tried in the accompanying case; namely, An open incision on the inner side of the foot, with division of the ligaments between the scaphoid osaleis and astragalus, also of the plantar fasciæ and a linear osteotomy of the neck of the astragalus. It is manifest that where the astragalus is distorted at its neck, if it is possible that the neck be so twisted that the facet should come facing forwards instead of sideways, that the danger of relapse to former deformity is diminished. McEwen and others have demonstrated the feasibility and utility of this method of correction in knock-knee, and also the freedom from risk. If the same method can be employed on the astragalus, it is evident that there is very slight subsequent distortion of the bone. It is manifest that beside osteotomy it is essential that all ligaments and tendons should be thoroughly divided. The dangers of suppuration are no greater than in excision of the tarsus and can be disregarded in severe cases where thorough asepticism is carried out.

CASE I. Boy aged seven, with congenital talipes varus of the right foot. After the usual precautions, an incision was made from a little way below the internal malleolus downwards and forwards, directly down to the bone, and extending to the head of the metatarsal bone of the great toe. The wound was held open by means of retractors, and using a long narrow knife the plantar fascia was thoroughly divided. The astragalo scaphoid, ligament and the fascia containing the insertion of the tibiales anticus and posticus were divided by direct incision. The scaphoid was found almost touching the top of the inner malleolus. On stretching the foot outwards the head of the astragalus could in part be seen. An osteotomy was inserted and driven three-quarters through the neck of the astragalus transversely to its normal axis. The foot was then twisted outwards and a cracking sensation felt as the remainder of the astragalus was broken similar to that felt in MacEwen's operation for knock-knee. Tenotomy of the tendo Achillis was then done, the incision sewed up, the foot dressed with aseptic dressings, and held in an over-corrected position by means of a fixed bandage (plaster-of-Paris) applied over the whole dressing, the foot being held until the plaster was hard. This was removed in a fortnight, and the wound was found healed without having caused any constitutional disturbance. A Taylor's retention appliance was then used, although there was no tendency toward recurrence of the varus deformity. The boy was seen four months later, and there had not only been no return of the deformity, but it was found that there was a slight valgus of the foot, resulting from the over-correction.

It would be incorrect to infer that such an operative interference as the above is indicated in many, even of the severer cases of club-foot, as in by far the

larger number permanent cure can be accomplished by less radical means. The measures mentioned may, however, be advisable in the severer forms with much osseous deformity when a prolonged treatment is impracticable or where such treatment has not been successful.

The need of thorough asepticism is, of course, manifest, for although the articulations of the joint are not opened, yet prompt healing without suppuration is essential to a perfect and speedy cure.

Two difficulties in the procedure may be mentioned: (1) The difficulty of a proper insertion of the osteotome in the neck of the astragalus. (2) The difficulty of keeping the incision by the osteotome in the proper line nearly transverse to the axis of the corrected foot.

A dissection and performance of this procedure on a cadaver will demonstrate the fact that the main artery and the articulations of the foot can be avoided.

THE VALUE OF SO-CALLED DIABETIC FOODS.¹

BY CHARLES HARRINGTON, M.D.,
Instructor in Hygiene and Assistant in Chemistry in the Harvard Medical School.

It is not my intention to attempt in any way to discuss the etiology or pathology of diabetes mellitus, a disease little understood even by those of large clinical experience, but to confine myself strictly to a consideration of certain foods, which are recommended as valuable in the diabetic dietary. It is, I believe, undisputed, that a most important point in the treatment of the disease is the more or less complete elimination of sugar and starch from the diet, and it is a natural corollary that the ingestion of these substances except in very small amounts, is often equivalent to the administration of a poison. This deprivation is borne with great difficulty by the average patient, and consequently substitutes for the carbo-hydrates have been sought for, to satisfy the intense craving for the forbidden articles of food.

Glycerine and the newly-discovered saccharin are said to satisfy in a measure the longing for sweets, but a perfectly satisfactory harmless substitute for starch has been more difficult of attainment. Various diabetic flours and biscuits have been prepared, and are widely advertised as being non-starchy, and as giving complete satisfaction to the patient. Having examined occasional specimens of biscuits and bread made from these flours brought me by physicians, and having never obtained any very satisfactory evidence of their value, I determined to secure as many different diabetic foods as possible, make analyses of them, and report the results, good or bad, to the profession. I have succeeded in obtaining eleven different kinds of flour and biscuit, advertised or recommended as substitutes for starchy foods; have examined them, and have now the honor to report the results to the Society. The foods, the claims that are made for them, and the results of examination, are as follows:

(1) Gluten Flour: Farwell & Rhines, Watertown, N. Y. This and the next-mentioned are quite extensively advertised as particularly adapted to the dietary of diabetics and dyspeptics. The circulars describe it as "substantially free from starch which is like poison

¹ Read at the Boston Society for Medical Improvement, February 27, 1888.

to the diabetic, and produces acidity, flatulence, and indigestion in dyspeptics." "It is as nearly free from starch as practicable to make a flour suited to general daily use." "The majority of diabetics find it just what they need." Examination shows moisture (at 100° C) = 8.69%, starch = 67.17%, which will produce sugar = 74.63%. A bread of this flour with the usual amount of moisture would contain over 30% of starch, or the equivalent of 35% of sugar.

(2) Special Diabetic Foods: Farwell & Rhines, Watertown, New York. This, according to the circular "is a flour for extreme cases of diabetes, a more crude gluten, pronounced by the highest authority to contain much less starch than the gluten imported from Paris at great cost." "As a diabetic flour it defies competition in this country or Europe." "Beware of hurtful imitations." The name of the "highest authority" is not given, nor is the amount of starch in the foreign gluten with which the comparison is made. Moisture = 8.10%, starch = 68.18%, which will produce sugar = 75.76%. Its bread would contain about 33% of starch, which will produce 40% of sugar.

(3) Health Flour. This brand was recommended very highly as a diabetic flour by a wholesaler, who claimed for it a great superiority over all others. It is not, I understand, very extensively advertised. Moisture = 8.03%, starch = 72.00%, which will produce sugar = 80.00%. Its bread would contain about 40% of starch, which would yield over 44% of sugar.

(4) Gluten Flour. New York Health Food Company. The company assert that "the foreign gluteins are found to contain a larger percentage of starch;" that "the gluteins offered by many millers, bakers and dealers, is simply ground bran and impure middlings, a sort of fine feed or offal of very small nutritive value aside from the liberal percentage of starch and the trifling proportion of gluten which it contains." It is further asserted that "the gluten manufactured by the Health Food Company is commended by the medical faculty as almost the only allowable and palatable bread food for the diabetic." Examination shows moisture = 9.30%, starch 66.18%, which will yield sugar = 73.53%. Its bread would contain about 35% of starch, which would produce about 38.5% of sugar.

(5) Gluten Wafers (plain). These were purchased at the agency of the same company and were guaranteed by the salesman to contain no starch, or at most, only the most accidental trace. The same guarantee was given for the Gluten Flour (No. 4), and for No. 6. Moisture = 8.10%, starch = 66.96%, which will yield sugar = 74.40%.

(6) Gluten Wafers (butter). These biscuits were represented as similar to No. 5, with the exception that they are made with butter, which proved to be the case. They are much more palatable than the plain biscuits. Moisture = 7.74%, butter not estimated, starch = 51.14%, which will yield sugar = 56.82%.

(7) Dr. Johnson's Educators. These biscuits are recommended very strongly by the seller, who assured me that they are absolutely free from starch. Moisture = 5.44%, starch = 71.43%, which will yield sugar = 79.37%.

(8) Boston Health Food Company's Diabetic Flour, No. 1. This flour and the next succeeding, (No. 9),

were sold as absolutely non-starchy, and in every way superior to all others for diabetics. Examination shows moisture = 8.13%, starch = 62.94%, which will yield sugar = 69.33%. Its bread would contain about 30% of starch, or the equivalent of 33.33% of sugar.

(9) Diabetic Flour, No. 2, (same company). Moisture = 7.66%, starch = 54.88%, which will produce sugar = 60.38%. Its bread would contain about 23% of starch, or the equivalent of 25.55% of sugar.

(10) Flour of Bran. This is sold as a pure bran flour devoid of starch and very valuable as a food. Examination shows it to be as nearly free from starch as possible, there being but a mere trace present. It seems to be a finely-ground washed bran. As to the claim that it is of value as a food, it may be said to be about as nutritious and palatable as exhausted sawdust.

(11) Carlsbad Wafers. These, I am informed by one of our prominent practitioners, are held in high favor by ladies of gouty diathesis, diabetics, and persons avoiding sugar on account of increasing portliness, by reason of a popular idea that they are made of white of egg and glycerine, to the latter of which ingredients they are supposed to owe their sweet taste. I very much doubt that a wafer of this degree of dryness could be made of these two substances, and I do not know that the manufacturers claim that they are so made, or that they are free from carbohydrates. However that may be, it is very easy to demonstrate that sugar enters very largely into their composition. They are made in three thin layers, the middle one consisting wholly of white sugar.

For purposes of comparison I have made three additional examinations of bread foods of acknowledged richness in starch, in order to determine whether it would not be as well, or better, in case a bread or biscuit must be given to satisfy the craving for starch, to allow a small amount of palatable ordinary bread or biscuit daily, rather than the more or less unpalatable and fraudulent substitutes.

As a fair example of palatable crackers, I chose Graham Wafers; the other bread foods were ordinary home-made white bread, and corn-cake made with "white meal." Graham Wafer, moisture = 3.94%, starch = 58.45%, (sugar = 54.94%).

Compared with the diabetic biscuits above mentioned, the Graham Wafer may be almost regarded as a superior form of diabetic food. It contains a smaller percentage of starch than the Educator with its 71.43% and the Gluten Wafer (plain) with its 66.96%, and but little more than the Gluten Wafer (butter) with its 51.14%. It is in addition a remarkably palatable food, while the other three are anything but pleasant to the taste, according to my own view and that of others who have tried them at my request. Moreover, the Graham Wafer is honest, while the others are fraudulent. Home-made Bread, moisture = 37.25%, starch = 44.99%, sugar = 49.55%. Corn Cake (white meal), moisture = 44.62%, starch = 38.04%, sugar = 42.37%.

In making my estimates of the amount of starch in breads made with the diabetic flours, I have supposed them to contain about the usual 40% (or thereabouts) of moisture. Comparing the estimated figures with the amounts of starch in the two ordinary breads, it is observed that the difference is but slightly in favor of the diabetic breads, whereas according to the claims

made by the manufacturers and retailers, the difference should be overwhelming. But the item of palatability is something to be considered, and the slight difference in the percentage of starch might well be waived in favor of the great difference in taste.

There is another and more serious side to this question of diabetical foods. That they are in the highest degree fraudulent has, I consider, been proved. They are in addition a positive danger, for the diabetic accepting as truth the assertions that they are non-starchy, takes into his system that which even the circulars of the manufacturers admit to be virtually a poison in its effect on the course of the disease, and thus innocently more than counteracts the benefit which he otherwise would derive from his medical adviser. In conclusion, I have to express the hope that every practitioner will do his utmost to discourage the use of these fraudulent and dangerous foods, and to drive them out of the market.

A CASE OF MACEWEN'S OPERATION FOR THE RADICAL CURE OF INGUINAL HERNIA IN A WOMAN SIXTY-THREE YEARS OF AGE.¹

BY G. H. MONKS, M.D.,
Surgeon to the Boston Dispensary, Surgeon to Out-Patients at the Carney Hospital.

The patient was admitted to the Carney Hospital on October 1, 1887, at a time when I was temporarily in charge of the surgical wards. She was small in stature, but well nourished and in remarkable good physical condition for one of her years. She could not remember that she had ever been sick in bed before.

She attributed the hernia from which she suffered to a fall about six years previously, shortly after which she experienced occasional "sickening pains" in the lower part of the abdomen, on the left side. The left labium became gradually enlarged, and there was pain in that region more or less constant, particularly severe during defecation. The patient had been advised to wear a truss, but she stated that with the use of one she had never been able to satisfactorily control the rupture. Eventually, the swelling became so large and troublesome that she was unable to get about. Being at this time in no condition to help herself, and becoming more and more a burden to her family and friends, she came to the Hospital, fully resolved to have anything done which offered a chance of cure.

An examination showed the existence of an inguinal hernia on the left side, of the size and shape of a large pear, the body occupying the left labium, and the neck extending to the external ring. The ring was so large that three fingers could be inserted without difficulty. The hernia was readily reducible.

Dr. A. T. Cabot saw the case in consultation, and, under the circumstances, advised operation. On October 12th, after the patient had been properly prepared, ether was given and the operation was carried out with thorough antiseptic precautions, Drs. Whitman and Monro kindly assisting.

The parts were shaved and rendered aseptic by washing with ether, and then with corrosive sublimate solution, with soap. A straight incision was made from the region of the ring to the lower extremity of the hernial protrusion, and this was deepened until

the sac was reached. The sac, which was unusually adherent, was then separated as carefully as possible from the adjacent tissues, partly by cutting and partly by tearing. The index finger introduced into the canal freed the neck of the sac.

It was then possible to separate with the finger-tip the peritoneum from the abdominal margins of the internal ring. The sac was now puckered up by a continuous suture of stout chromicized catgut, in the manner recommended by MacEwen, and the needle was pushed through the abdominal wall from behind forwards. On drawing upon this suture, the puckered sac was with the assistance of the finger made to occupy a position within the abdomen, where it considerably overlapped the margins of the inner ring. The suture, thus drawn tight, was made fast in the muscles of the abdomen. The walls of the canal were now drawn together with chromicized gut, so that the conjoined tendon and Poupart's ligament should be approximated as closely as possible. It was now evident that it would be impossible, on account of the size of the cavity left after removal of the sac, to sew up the wound in the ordinary way without leaving pockets. A large number of sutures of fine catgut were, therefore, buried, and the margins of the wound brought together with a continuous silk suture. No drainage was used. Iodoform was sprinkled on the wound, and flexible collodion, layer after layer, with strips of cotton. This was covered with a large pad of absorbent cotton kept in place by a firm T-bandage.

The patient rallied from the immediate effects of the operation, but the recovery was complicated by a failure of the wound to unite in that part superficial to the external ring. It is difficult to say whether this was due to some defect in the antiseptic precautions or to the age of the patient, which was certainly unfavorable for rapid repair. The deep sutures apparently held the walls of the inguinal canal in perfect apposition. The condition of the parts gradually improved by the free use of antiseptic solutions, and the wound slowly healed by granulation. The patient now sits up a few hours each day.

There has never been any sign of a recurrence, though no bandage or pad of any kind has been used since the first few days succeeding the operation.

I report this case as interesting on account of the age of the patient, but am well aware that no case should be considered cured until a period of, at least, one year has passed without recurrence, during which time no artificial support of any kind has been worn. It certainly does not seem to be advisable to attempt a radical cure in old persons, except in such cases as insist upon an operation, after they have been made acquainted with the dangers, as well as with the chances of recovery and of a permanent cure.

A CASE OF MACEWEN'S OPERATION FOR THE RADICAL CURE OF CONGENITAL INGUINAL HERNIA IN A BOY.¹

BY ROYAL WHITMAN, M.D.,
Surgeon to the Orthopedic Department at the Boston Dispensary.

The patient, a boy eleven years of age, was brought to me with a left serotal hernia, which had existed since birth. Various trusses had been applied with

¹ Read before the Suffolk District Medical Society, Surgical Section, January 4, 1888.

¹ Read before the Suffolk District Medical Society, Surgical Section, January 4th, 1888.

but partial relief, and finally their use had been abandoned. Both mother and child were anxious for a radical operation, as the affection prevented the boy from playing with the other children, and was the cause of more or less continual discomfort, with at times severe pain. The hernia was about the size of an orange. The external opening admitted two fingers, the bowel slipping easily in and out of the abdominal cavity.

On May 9, 1886, eight months ago, I performed MacEwen's operation, assisted by Drs. Monks and Conant. The sac of the hernia, congenital, was easily dissected out, divided above the testicle, separated from the cord and returned to the abdominal cavity, the lower segment being sewed together over the testicle to form the tunica vaginalis. The sac was attached to the abdominal wall, and the canal closed with thick chromicized gut. The wound was closed with fine gut, several strands of which being placed superficially for drainage. The dressing consisted of iodoform gauze, covered with a thick pad of corrosive sublimate cotton, and held in place by a T-bandage of thin sheet rubber, which provided equable pressure, and prevented any contamination of the dressing. The leg was then flexed upon the body, and securely bandaged to a bent wire frame, known as the "Cabot hip-splint." This apparatus was of great service, preventing the child from tearing off the dressing; and I should strongly recommend its use for children, where, as in this case, constant attendance cannot be provided. In any event, too, this immobilization of the leg must materially aid in the cure.

During the night there was retention of urine, and afterwards elevation of temperature, which rose to 103° on the third day. The superficial stitches were then removed and the wound explored, but nothing was found to account for the fever except some induration about the parts. The temperature then fell to normal. On the twelfth day when the dressing was removed the wound had closed. During the third week the child who is now presented for examination, was about as usual, and has since suffered no discomfort, no bandage or support having been worn.

Reports of Societies.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.

F. B. HARRINGTON, M.D., SECRETARY.

FEBRUARY 27, 1888, the President, DR. O. F. WADSWORTH, in the chair.

RESULT OF RESECTION OF THE ANKLE-JOINT.

DR. CABOT showed eight cases of resection of the ankle-joint illustrating the final result that can be hoped for from this operation. Tracings made by Mr. C. L. Scudder from several of the cases, were also shown; which gave the mobility of the diseased joints as compared with the well ones. The patients had all been treated at the Children's Hospital, and were not selected cases, as all of those operated upon by the reader, whose addresses he knew, had been sent for, and all of those who responded were shown.

The periods elapsed since the operation varied from one to seven years, and the joints were all solidly

healed and free from tenderness or swelling. In one large girl operated upon seven years ago, in whom the astragalus and a considerable portion of the lower end of the tibia and fibula with the malleoli, were removed, there was a tendency to pes varus, not sufficient, however, to cause inconvenience. The joint was firm and caused no discomfort, although she was constantly on her feet.

One rather puny boy had a slight degree of pes equinus, but with these exceptions the joints were in good position. In several instances, the bones removed, were shown with the patients. In all of the cases the disease was a caries of the smaller bones, often affecting the ends of the long bones and probably always tuberculous in character. In one case, disease of the knee-joint (white swelling), and in another, caries of the lower dorsal vertebrae complicated the condition.

The reader said that this operation was often, perhaps usually, unsatisfactory in adults, but that in children it almost invariably resulted in cure and in the restoration of a useful joint, as the cases present would help to show. He then went on to say: "In regard to the operation, the first important thing is the thorough removal of all diseased tissue, osseous, cartilaginous and synovial. In my earlier cases I often tried to limit the operation to the parts evidently diseased, and scraped out the softened portions with a sharp spoon. In dealing with the small bones, however, I soon found that the part left, almost certainly became affected with the disease and had subsequently to be removed, so that I later adopted the plan of removing the whole of any of the small bones which showed unmistakable caries. The only exception to this rule was made in cases of caries of the os calcis, in which the disease seemed to be wholly extra-articular. Of the longer bones the metatarsals were treated by the removal of the diseased ends.

When we come to the tibia and fibula, we have strong reasons for trying to save all of the healthy bone possible:

First: Interference with the epiphysal cartilage checks the future growth of the limb and may unnecessarily add to the shortening.

Second: The malleoli when they can be preserved add greatly to the strength and steadiness of the new joint. The shortened foot falls in between them and they give it much lateral support. It is therefore better, when possible, to thoroughly scrape out the diseased tissue in these bones and not, except in extreme cases, to saw off the ends evenly.

Several of the cases here this evening show, however, that even when the malleoli are lost, a very useful joint may still be obtained. After the removal of the bones the diseased synovial membrane should be carefully dissected out. This brings us to speak of the incision used in these cases. I have always used the old method with two lateral incisions, which avoid the injury of any tendon or vessels, and which I have found to give easy access to all parts of the cavity. The incisions should be of good length, as the thoroughness of the operation is important, and the skin readily heals.

In the after-treatment, one or two points seem worthy of attention: In the dressings, iodoform is a valuable auxiliary, as it seems to have the power of checking any subsequent tubercular formation which might start from small portions of granulation tissue, overlooked in the dissection. A seton of iodoform

gauze is kept through the joint from side to side until the wound has healed about it, and when it is finally withdrawn the sinus usually soon closes.

When the wound does not contract healthily and the granulations assume a pale, flabby look, it is usually evidence that the tubercular process has not been eradicated, and a second operation with the erosion of the granulation tissue and the thorough inspection of the bones, is usually wise. It is further of the first importance that these ankles should be kept immovable, not only during the healing process but for a considerable time (several months), after the joint is apparently sound. While dressings are necessary, I usually treat these cases on a posterior wire splint, such as I show here:

Wire Splint with padding for Leg and Foot.

Behind the ankle and heel the wire is covered with rubber tubing.

This is made of an iron rod $\frac{3}{16}$ of an inch in diameter, which after being bent to fit behind the leg, is padded for the reception of the calf and foot, while the wire which passes the ankle is left unpadded, but is protected with rubber tubing drawn on over it. This splint should reach to the middle of the thigh, and should be slightly bent at the knee to prevent the leg from turning upon it. With this last object in view, care should be taken not to make the splint wider than the leg, so as to allow lateral motion. With attention to these details, very perfect fixation can be obtained, and the dressings can be easily changed without removing the splint. After the wounds have healed, a plaster or silicate bandage may be applied, and the patient allowed to go about with crutches and a high shoe on the well leg. In one or two of my earlier cases, in which I neglected fixation after healing, the wound broke out afresh when the joint was put in use, but quickly closed when it was again immobilized.

DR. E. H. BRADFORD said these cases of Dr. Cabot are of value in showing what may be gained by the operative treatment. A short time ago, Dr. Gibney, of New York, showed some excellent results from conservative treatment. Dr. Cabot, by these cases, has shown that much time can be saved in the treatment. The value of curetting is not great when applied to the ankle joint. This can readily be understood when we consider the anatomy of the joint. He preferred plaster-of-Paris bandages for fixation after operation to the wire splint in small children, because he thought it gave better fixation.

There is great danger of relapse of the tubercular condition, and for this reason the new-formed tissues should be protected for a long period. He is in the habit of using a Thomas splint after operation during the convalescence. It is important to protect the inflamed joint not only from motion but also from jar, and by means of a Thomas splint locomotion is possible with fixation of and protection to the joint.

Dr. Bradford has of late been using the method of Kocher¹ in operating. This method gives a very excellent view of the joint. A curved incision is made under the external malleolus backward to the external

border of the tendo Achillis. This incision divides the peronei tendons and the lateral ligaments. These tissues are reunited by suture at the end of the operation, care being taken to reunite appropriate tissues. The foot, after the incision has been made, is forcibly inverted, and a very excellent view of the joint is obtained. The astragalus can then be easily removed, and other bones if necessary.

DR. H. W. CUSHING said: Fixation of the ankle, as has been already stated by Drs. Cabot and Bradford, is a very important element in the subsequent treatment of these cases, not only directly after the operation, but during the time when the patient is discharged from the immediate care of the surgeon. This favors apparently the closure of sinuses, and certainly prevents the subsequent deformities which are occasionally seen in cases which, at the time of discharge, were in good position. This prolonged fixation gives an opportunity for the necessary consolidation of tissues to take place before the ankle is called upon to bear the weight of the body. It has been found that a tin shoe for fixation of the ankle is a useful addition to the "Thomas" knee-splint alluded to by Dr. Bradford, since it, in addition to fixing the ankle, can be removed without inconvenience for necessary changes of dressing, and the condition of the seat of operation more easily controlled than where a fixed bandage, as plaster-of-Paris or silicate.

DR. CABOT said that he was much interested in what Dr. Bradford said about Kocher's incision; he had often intended to try it, but had adhered to the old method from force of habit. He had always found it possible with the two lateral incisions to inspect all parts of the joint, and had sometimes passed two strips of bandage through from side to side, with which the assistants could pull the soft parts forward and back, and thus hold the wound widely apart. The lateral incisions have also an advantage when it is necessary to carry a saw through the joint for the removal of the ends of bones.

RUPTURED OVARIAN CYST.

DR. F. B. HARRINGTON showed an ovarian cyst which had ruptured in the abdominal cavity, allowing its contents to escape among the intestines, causing considerable peritoneal inflammation. The cyst-contents, which weighed twenty-two pounds, were jelly-like and very tenacious. The patient's age was forty-two years. She was unmarried, and apparently in good health. A portion of the omentum was removed with a mass attached to it, resembling, but somewhat harder than the contents of the cyst. It was impossible to say how long the rupture had existed. The patient was doing well.

DR. FITZ stated that the microscopic examination of the gelatinous material showed a homogeneous substance giving the reaction of mucine. It contained large, round cells in considerable number. The diseased part of the omentum was a tissue of an alveolar structure, the meshes being filled with the jelly-like substance. No traces of clusters of epithelioid cells were found. Numerous fibrous sprouts were seen projecting into the gelatinous mass, and their tops were covered with elongated cells, in which were hyaline globules.

The appearances corresponded with those which have recently been described as a pseudo-myxoma of the peritonium. The suggestion is that the gelati-

¹ Arch. f. Klin. Chir., 1886-87, xxxiv, 318, 328.

nous contents which have escaped from the cyst have produced a certain degree of peritonitis, and are traversed by fibrous growths from the peritoneum. The gross appearances are suggestive of malignancy, but the structure gives no evidence of a cancerous growth.

Dr. JOHN HOMANS called attention to the adhesive quality of the mass. He said it could not be called a fluid. He had seen such cyst-contents several times, but it was not common. The cyst-wall was usually very thin—much more so than in the specimen shown. In his experience the pedicle had always been very small. When the contents escape into the abdominal cavity it is very difficult to remove, as it clings to the intestines with great tenacity. His cases had all recovered from operation, but two of them had subsequently died with what seemed like malignant growth. In one of these latter cases he had found hairs in the cyst, and some time after the operation an opening was formed into the bladder, through which, from time to time, particles of hair escaped. As a result of the accumulation of hair in the bladder a stone was formed, which he subsequently removed by operation.

In reply to Dr. Homans, Dr. HARRINGTON said that the pedicle in this case was not remarkably small, being as large as two fingers.

Dr. CHARLES HARRINGTON then read a paper entitled

THE VALUE OF SO-CALLED DIABETIC FOODS.²

Dr. E. S. WOOD said that he had looked up some notes of some analyses which he had made a few years ago; he found that his results compared very closely with those of Dr. Harrington. At one time Dr. Bowditch sent to him for analysis a diabetic flour, which the manufacturers represented to be free from starch. This was found to contain $70\frac{1}{2}$ per cent. of sugar when the starch had been converted. The manufacturers were informed of this, and they then sent a sample containing $39\frac{1}{2}$ per cent. This shows that by using care the amount of starch may be much reduced.

Ordinary Graham flour yielded a little over 70 per cent. of sugar. He had found that two samples of Paris diabetic bread had yielded—one about 27, the other about 37 per cent. of sugar.

Dr. F. C. SUATTUCK expressed his appreciation of the service which Dr. Harrington had rendered in so clearly demonstrating the grounds for the belief held and acted on by many members of the profession, that the claims of the so-called diabetic foods are fraudulent. In a paper read before the American Medical Association some years ago, Dr. Austin Flint—then Junior—remarked on this fact, and advocated giving ordinary bread rather than any of these patent foods, if bread in any form were given at all: thus the physician knows what he is doing, at all events.

Physicians are partly, but not wholly responsible for the popularity of these foods. Patients take advice from their friends, as well as from their doctors, and diabetics soon find fellow-sufferers, ready with suggestions. Some are unwilling to carry out as strict a diet as is desirable for a sufficient length of time, and deliberately transgress; others are deluded directly or indirectly by these swindling claims.

Some years ago, a lady asked the speaker if she might take the diabetic bread of the New York Health Food Company, and said that a diabetic acquaintance

enjoyed it very much. A sample was procured and given to Dr. Harrington for analysis, who found about 70 per cent. of sugar-forming material. Very recently, a young man sent by Dr. Greenough with a urine containing 8+ per cent. of sugar was given minute directions as to diet, and told to report again in five days. At the expiration of that time the urine showed that the directions could not have been followed, and it was found that the patient had laid in a supply of diabetic crackers at Dr. Johnson's Educator Establishment; he carried the crackers in his pocket, and eat them freely between meals, having been assured by the clerk that they contained no starch. The crackers were interdicted, and when the urine was examined again at the end of five days sugar had disappeared.

There are doubtless many diabetics who are the victims of this knavery.

The diabetic preparations of the Health Food Company receive a practical endorsement in the article on "Diabetes" in "Pepper's System of Medicine."

The *New York Medical Journal* of January 7, 1888, contains a receipt for a substitute for bran-bread, which is found useful and grateful by a patient of the speaker. The only sugar-forming material it contains is the small percentage in the baking-powder. It is as follows: Beat six eggs, add one teaspoonful of baking-powder—or its chemical equivalent—one-fourth teaspoonful of salt, and beat again. Pour the mixture on a hot waffle-iron smeared with butter, and bake in a very hot oven. Powdered nuts may or may not be added. Eat hot with butter or cheese, or they will keep well, and may be eaten cold.

Dr. B. F. DAVENPORT said that what analyses he had made had resulted about the same as those of Dr. Harrington. He had been surprised at the amount of starch which he had found in ordinary bran—some 30 per cent.—but thought a bran could be prepared which would contain as little starch as macaroni or vermicelli.

Dr. HARRINGTON remarked that the "bran-flour" which he had examined contained a quantity of starch too small for chemical estimation, and that he had found it to be a very difficult matter to estimate starch in any form of bran, on account of the inevitable conversion of a large part of the cellulose into sugar by the action of the dilute acid, which might account for Dr. Davenport's very high figures. He had examined some samples of macaroni and spaghetti, hoping to find a low percentage of starch, in which event they might be recommended as substitutes for bread; he had, however, found upwards of 80 per cent. of starch.

Dr. G. K. SABINE said: Knowing the result of the analysis of some of the diabetic foods, and, in fact, many of them, I have been accustomed for a long time to have a bread made of Graham-flour and nice, clean wheat-bran in equal parts. As the whole wheat or Graham-flour contains a little more than seventy per cent. of starch, this mixture reduces it to the amount contained in some of the best specimens of diabetic flour. A patient of mine has succeeded in making the bread with a large number of eggs, butter, and baking-powder, in the form of biscuits or gems, so that each one contains, at least, half an egg. The advantages of it are that it is nutritious, palatable, and easily and quickly made, requiring only about twenty minutes for that purpose, and the amount of sugar-forming material is constant, not varying with differ-

² See page 286 of this number of the Journal.

ent specimens. Another advantage which it possesses over ordinary bread is its bulk, a property of no little importance, as diabetic patients frequently insist on having fairly large quantities, no matter what may be the character or composition of the bread.

Dr. R. H. FITZ thought that Dr. Harrington's investigations were likely to prove of especial value to physicians, as forcibly reminding them of what they may have forgotten. His results confirmed most satisfactorily the statement of Ferrieh's, that the various substitutes for starchy foods usually contained more or less starch. He, therefore, recommended the use of ordinary bread in place of these substitutes.

A diabetic patient under Dr. Fitz's care for a year and a half was daily allowed a certain quantity of Graham-bread. During this time his weight and strength increased, while the daily quantity of urine diminished from six quarts to less than three quarts. Death eventually resulted from pneumonia with coma. He was constantly provided with almonds, and ate them between meals, when hungry.

It might be doubted whether Dr. Harrington's analyses could lead to a verdict of fraud against the manufacturers of the so-called diabetic foods and their agents. There are mild cases of diabetes which improve under a restricted diet, and severe cases which grow worse, despite the diet. There can be no question that under the restricted use of bread made from flour, called anti-diabetic, some cases will improve as they grow better under the limited use of ordinary bread. The manufacturer can undoubtedly show, as in the case of Dr. Rotch's patient, that certain diabetics improve while using their food. In the light of such evidence, a jury would not be likely to form a verdict of criminal fraud.

Dr. HARRINGTON answered that, in his opinion, the statutes relating to the sale of foods and drugs covered such fraudulent articles as these diabetic foods, and he had no doubt that an indictment could be drawn which would lead to a verdict for the Government. He did not believe that in such a case the defendants could show that the improvement spoken of was due to the use of *diabetic* flour, or that it would not have occurred with any other ordinary flour used in moderation. In any event, he was of the opinion that, under an indictment for fraudulently selling as non-starchy an article containing as much as sixty-five or seventy per cent. of starch, which substance they state in their circulars to act as a poison to the diabetic, the court would rule that evidence as to benefit derived from its use would be irrelevant and inadmissible.

Dr. GEORGE B. SHATTUCK expressed a fear that "diabetic foods" containing starch would continue to find the same market with sufferers from diabetes that the cures for the opium habit, containing some form of opium, have with those addicted to the opium habit, and the remedies for the alcohol habit, which contain alcohol, have for re-forming drunkards — and this in spite of such good work as that done by Dr. Harrington, and in spite of the protest of the profession.

In a recent case of diabetes under his care, in a young girl ten years of age, where the ultimate prognosis was unfavorable, the patient and her mother eventually refused the annoyances of restricted diet, calmly preferring immediate comfort and a possibly earlier termination.

Dr. JOHN HOMANS was struck by the prevalence of diabetes at the present time, and its apparent increase. Something is due to more careful investigation, and yet he felt that the disease must be on the increase. He had recently seen a number of cases in private practice.

Dr. C. E. STEDMAN said that he had not had half a dozen cases of diabetes under his care in the City Hospital in fourteen years. In the last few years he had seen a number of cases in private practice.

Dr. E. N. WHITTIER said that in the last four months, at the Massachusetts General Hospital, there had been four cases under his care. He had found the insatiable appetite the most difficult thing to contend with. He recommended a coarse Graham-flour, rolled out into very thin sheets or sticks. Most diabetics insist upon a certain amount of bread. Cases of diabetes are frequently seen in out-patient departments.

SUFFOLK DISTRICT MEDICAL SOCIETY. SURGICAL SECTION.

G. H. MONKS, M.D., SECRETARY.

MEETING, Wednesday, January 4th, the chairman, Dr. J. COLLINS WARREN, presiding.

Dr. E. H. BRADFORD presented a communication on

OPEN INCISION IN WRY-NECK, CONTRACTED KNEE, AND TALIPES VARUS.¹

Dr. M. H. RICHARDSON said: I would like to ask Dr. Bradford under what circumstances he would consider it necessary to remove the plaster in order to change the dressings.

Dr. BRADFORD: Of course if there were constitutional symptoms, high temperature, etc., indicating the possibility of sepsis, the plaster should be removed and the wound inspected. There is usually some elevation of temperature the first night from the disturbance of the operation, but after that everything, as a rule, goes on well.

Dr. RICHARDSON: It seems to me that the operation on club-foot, as described by Dr. Bradford, avoids one of the great dangers existing in former osteo-plastic operations; namely, the opening of the synovial cavities of the tarsus. I think that such an operation may often be done without involving them. The less we lay open the synovial cavities the more favorable is the prognosis, and it seems to me that that operation is to be selected which, on the whole, renders septic infection of the joint least probable.

Dr. WARREN: I would say in regard to open incision in place of subcutaneous incision, that the small experience I have had shows that there is a little difficulty in managing the integument of the part where an incision has been made and the parts dissected away beneath and then stretched. The result is a lack of coaptation of the skin to the soft parts below, and a considerable delay in the union of the parts consequently. I have in mind a case of Dupuytren's contraction where I did the operation on both hands. On one hand a long incision was made, exposing the band, which was subsequently dissected out, after the skin had been removed from its surface. On the other hand I merely made a few subcutaneous incisions. In the latter case

¹ See page 288 of the Journal.

the wound healed rapidly, whereas in the former it was two or three weeks before firm union of the tissue had taken place, and the wound had ceased to secrete. I don't know that it is a disadvantage in all cases of deformity which are treated in this way, but at the same time it does not make the operation quite as simple as one would suppose where with antiseptic precautions one expects to get rapid healing.

DR. MIXER: There is one point in regard to this class of operations where the bone is partially chiselled through, and which shows particularly well in the specimen of Dr. Cabot's, referred to by Dr. Bradford, (and also on the caliver); namely, the forcing together and locking as in an impacted fracture of the fragments. The part that is not cut makes a sort of a lock that does not break, but bends. It may not do so in this operation, as the force is applied in such a manner that the fragments may be more inclined to separate than in MacEwen's operation. This kind of impaction probably tends to hold the parts more firmly in position, and to hasten union.

DR. KINNEAR: I would like to ask Dr. Bradford whether in any case of tenotomy the muscles ever became strong again. Are the legs as strong as if the tendons had not been cut?

DR. BRADFORD: That would be a physiological question pretty hard to answer, and I do not know. I cannot answer positively from the results of experiments on animals, but my impression is that they do recover their strength. Certainly so far as we can tell from clinical results. they do.

DR. KINNEAR: Would it be so also in children over ten or fifteen?

DR. BRADFORD: If we compare cases that have not been operated upon by cutting (but where the tendon has been stretched) with cases that have been cut, I should say that the strength in one case is as great as that in the other. I refer to cases that have been watched several years.

DR. KINNEAR: I ask because we naturally suppose that the muscle would not have the same contractility as one that had not been operated upon.

DR. BRADFORD: Theoretically you would say so, but clinically the difference seems hardly noticeable.

DR. KINNEAR: The reason I ask the question is because it seems to me that the nervous lesion connected with the contraction of muscles is a subject which will occupy the attention of the profession a good deal in the future. Taking contraction of all kinds, it is a very wide subject. You begin with twitching of the muscles, which is a slight clonic contraction. Then you get real clonic contractions of the muscles, which last a very short time. Then tonic contraction, and then chronic contraction. The nervous influence is, without doubt, very powerful.

In a case that I saw last year one of the symptoms was that the head was suddenly drawn backwards some dozen or more times a day, to the terror of the patient. It was held there for a few moments each time. It was treated by ice to the spine, drawing blood, as I supposed, from the cells producing the contraction and it was overcome. After four or five weeks the patient entirely recovered. In a case that Dr. Chapman reports in a work on Neuralgia, an adult had a tonic contraction of the splenius and the trapezius, which was accompanied by neuralgia, and there was great tenderness over the second cervical vertebra. This head would jerk over to the right

side. By the application of ice to the whole length of the spine, in the course of ten days the trouble was entirely overcome, and the patient got well. He records other cases of chronic contraction, which were entirely cured, after lasting several years, by the application of cold to the spine, showing apparently that the central nerve cells must be in many cases the origin of the contraction of the muscle itself.

The point which I wish to bring up is simply whether, in many cases, such as for instance the contraction of the sterno-mastoid muscle, whether such an application might not very well overcome such a contraction without any operation at all, so that if there is a loss of contractility in the muscles produced by an operation, e. g. tenotomy, whether such a loss might not be prevented by having no operation at all in quite a number of cases. I don't mean to apply it to all cases, but to a great many. I thought it would be an interesting point in connection with Dr. Bradford's paper.

DR. BRADFORD: In regard to that matter there are a certain number of cases of wry neck that could undoubtedly be corrected without operation, but in cases where tenotomy is done there is a certain degeneration of the muscles themselves, whatever the original cause may be. Here, of course, the condition of the muscles is such that no alteration in the cells of the spinal cord would affect the fibrous tissue substance which is no longer muscular. In that case I think tenotomy would have to be done.

DR. ROYAL WHITMAN then read a paper on a

CASE OF MACEWEN'S OPERATION FOR THE RADICAL CURE OF CONGENITAL INGUINAL HERNIA IN A YOUTH.²

He showed the patient, and exhibited large diagrams copied from MacEwen's original article in the *Annals of Surgery*.

DR. G. H. MONKS followed with a

CASE OF MACEWEN'S OPERATION FOR THE RADICAL CURE OF INGUINAL HERNIA IN A WOMAN SIXTY-THREE YEARS OF AGE.³

DR. H. O. MARCY said: As the gentlemen of the Section know, I am deeply interested in the cure of hernia, and believe it is now conceded that I was the first to advocate and put in practice the open method of dissection and closure of the parts by buried animal sutures.

The operation under discussion, of Professor MacEwen, has been known to me for some years. I think it has many features which commend themselves to your approval. The author emphasizes as distinctive the treatment of the peritoneal sac. His method of intra-folding, without opening, is the essential point under discussion.

As will be seen in some of my earlier publications, I emphasized the importance of obliterating the sac for the same reasons advocated by Professor MacEwen. My attention, was directed to it many years ago by our distinguished pathologist, the late Dr. J. B. S. Jackson as a factor causing often the return of the hernia. I do not now recall a single surgical author who had mentioned it, in this relation, before the reading of my paper upon "Hernia" at the International Congress in London, 1881. Before this I

¹ See page 288 of the Journal.

² See page 288 of the Journal.

had treated the sac in various ways, sewing through its base and returning unopened, transfixing it through with the ring, etc. To all these procedures there appeared to me a marked objection. With the peritoneum, it seems clear, there can be no probability of reinforcing a weakened ring. The object to be attained is to leave a smooth, unobstructed peritoneal surface, over which, avoiding friction or interference, the semi-fluid intestinal folds may easily glide, without a depression to receive an impulse therefrom, and thereby cause a possible return of the hernia.

This does not appear to be the object sought by the author, since he thinks there is an advantage from the projecting button which he hopes may result therefrom, deflecting an impulse in another direction. Before the perfection of our antiseptic methods of operation, it can easily be seen that there was a distinct gain in not opening the peritoneum. Now, in the hands of competent operators, I suppose few would think the danger greatly increased by a free dissection. Not seldom is the opening of an old and thickened sac, filled with adherent omentum, rendered a necessity; very likely, also, the resection of its contents. I cannot help thinking, it is usually much safer to open an old sac and know the condition of the parts, and thereby, as in no other way, protect the abdominal contents in its closure. In due deference to an excellent authority, for whom, personally, I have the highest respect, I beg leave to differ from Professor MacEwen, since it seems a clumsy, unscientific method of treating a redundant, oftentimes half disorganized tissue, the theoretic resultant of which would, if attained, in my judgment be detrimental. The twisting of the sac and then ligating its base, as recommended by Dr. Banks, appears preferable in case of operation and in result; but both methods seem to be dominated by the teaching of all save recent surgery, where the treatment of the peritoneum by any method was undertaken with fear and trembling. In the large umbilical or abdominal hernia, would Professor MacEwen or his followers advocate this disposition of the redundant peritoneum? and if not, why not?

If we consider hernia in its essence, regardless of its particular variety, as a yielding of the abdominal wall, whereby its contents are displaced or extruded, then is not the surgical problem, the restoration as nearly as possible to the normal standard, the theoretic solution? If nature demanded the buttressing the parts by a "button," why are we not all thus provided in advance? Let us believe that nature, in her wise conservatism, soon disposes of the redundant tissue thus ingeniously left. In my judgment, Professor MacEwen is much more scientific and happy in result, from the careful way in which he closes the abdominal rings. I cannot doubt the method excellent, and the good results due in great part to his carefully placed buried sutures.

As early as 1870, I first began their use in operation for strangulated hernia, and, surprised at the result, I began a careful laboratory study of the histological changes incident to the burying of animal sutures in rabbits and dogs. To my delight, I found there was an active proliferation of connective tissue about the suture, which in itself had the appearance of having been vivified, doubtless replaced cell by cell by connective tissue.

This was the basis of my premises for the new op-

eration for the cure of hernia by open dissection and suturing. I have twice had the opportunity of making sections through the parts, after operating for hernia followed by cure, where death supervened some months after from other causes. Here similar results were also distinctly seen, and the peritoneum was perfectly smooth, without depression. These specimens were shown to the Society.

Earlier I resected the peritoneum, and coapted with a continuous over-and-over suture of gut or tendon: now I prefer to open the well-freed sac, and, the edges held by an assistant, with the finger within the cavity for protection of the parts, sew in a continuous even seam with a double kangaroo chromicized tendon. This I devised more than ten years ago, using a curved needle, not very unlike that of Professor MacEwen, the essential of which is the eye near the point, since thereby a double sewing-machine stitch can be made, threading the opposite end and withdrawing, thus carrying the sutures in opposite directions through the same puncture. This is repeated in stitches, not to exceed one-third of an inch, until sewed across. One knot suffices, regardless the number of stitches, an important desideratum with animal suturing. When the redundant sac is resected the peritoneum is returned. Then, with a larger needle and tendon, the refreshed walls of the ring are carefully approximated by sutures in a similar way. Sometimes the overlying fasciæ is also independently thus brought together and the external wound closed by an over-and-over continuous suture. Unless the abdominal wall is fat, I find it better to omit drainage and then seal the wound with iodoform collodion; over all, a wool-pad dressing.

I have operated in this manner over fifty times without the loss of a single life, excepting strangulated cases, where the abdominal contents were involved, and although I have not been able to trace the results in all cases, I am sure not less than seventy-five per cent. are known cures. I am glad to listen to the discussion of hernia and see the excellent results obtained, since I feel the operation by the open method a great advance in modern surgery. To relegate so many of our patients to lifelong suffering and a more than possible danger, is an *opprobrium* to our art.

DR. BRADFORD: I have had, I think, five cases of MacEwen's operation, and one of an operation recommended by Mr. Paul; namely, the twisting of the sac. I can only corroborate what has been said about the advantages of the operation and which are clearly stated in Mr. MacEwen's paper.

DR. MARCY: When I discuss the disadvantages of puckering, I discuss them as Mr. MacEwen does, theoretically, and all we may know about it is what we may get from the operation. The danger to the peritoneum, it seems to me, would be this: it makes a point against which something may be brought into contact, to the detriment of the peritoneal contents. If it is left alone we get a depression, a pocket, and that acts toward making it easy for the return of the hernia. I suppose this occurs in the way that has been recommended of sewing the sac into the ring, in which I have also had a considerable experience, because it holds and fixes the peritoneum to the point, and does not allow an easy gliding of the surfaces. In other words, it makes a point of fixture, and perhaps tension.

DR. BRADFORD: Do you think you can sew the edges of the sac together so that the peritoneum at that point can become as tense as the abdominal wall?

DR. MARCY: I believe it.

DR. BRADFORD: Then Dr. Marcy's experience differs from that of other surgeons. Other surgeons have not been able to get that theoretical result that Dr. Marcy claims.

DR. MARCY: I have just reported two cases where the surfaces were as smooth as if there had been no hernia.

DR. BRADFORD: The statistics, as collected, show that the results, as far as we can get at them, so far as prevention and relapse are concerned, are not so good as those reported by Dr. MacEwen. Although it is a comparatively recent operation, still we can see the results for eight or ten years, and though very good results can be obtained by the method described by Dr. Marcy, I think he is rather sanguine if he thinks that other surgeons are likely to be as successful as he has been in that respect. My experience has been simply with children, and the results have been very satisfactory.

The method introduced by Mr. Paul with the idea of giving an operation introducing the torsion method, I tried in one case, and, although the case was successful, I think MacEwen's method is rather preferable.

DR. MARCY: Pardon me a moment more. I was lead up to this operation in two ways. First, I ligatured the base of the sac, and then returned the whole peritoneal pouch *en masse*; which would be a modification of the MacEwen operation of puckering it into a mass and returning. That was unsatisfactory in a certain measure. I obtained good results, but at the same time it did not seem to me that the operation was so easy, or the convalescence was so rapid. Again, in a certain class of old and large cases I puckered it, and purposely sewed it into the ring. That is not original with me. But the cure was not so satisfactory or easy.

Then, reasoning still further upon the subject, (and so far as I know I was the first one to call the attention of the profession to this), the sac was drawn well down and then resected, the stump sewn through and through, and then returned, as I have described. That I do believe is preferable to the method of MacEwen. The other steps of his operation are not so different from my own, although I use a great deal more suturing than MacEwen.

DR. BRADFORD: Of course it is too much to claim that any one method would be desirable in all cases of hernia, and I don't think Dr. Marcy would claim that his method should be used in every case. You must cut your pattern according to your cloth. When you have a large ring you must act differently from what you would when you have a small ring.

If we have a case with the sac glued down, we cannot do as well as when the conditions are otherwise. I cannot see why Dr. Marcy should be so sweeping in his condemnation of the method, which has been pretty thoroughly followed out. It has certain advantages in some cases; it cannot be done in all cases. But I still think that in a child with congenital hernia the operation as described by Dr. Marcy could not be done. The sac is too thin. You cannot sew it. You can bunch it up. No matter how many times you

sew it you would find it difficult to get so firm a plug as in the way advised by MacEwen.

DR. MARCY: I would like again to say that I don't think it is wise to make a plug out of the sac. It is faulty in so far as you rely upon it as a plug. Professor MacEwen does not attempt that as I understand it. He simply intends to keep something on the inside that prevents the intestines coming out. He does not use it as a plug.

DR. BRADFORD: Perhaps Dr. Marcy is right. I should call it a cover, perhaps. I say that the objections that Dr. Marcy has advanced, which are theoretical objections, have been refuted by practice.

DR. MARCY: I am perfectly willing to leave it open to personal opinion. I am glad to have the matter brought up. I think that anything which calls the attention of the profession to hernia is a distinct gain. We have been too fearful about operating.

DR. S. N. NELSON: If the sac which is put back in the MacEwen's operation remains free, as is presumed by the operator, it seems to me, especially if there be any weakening of the abdominal walls, that it acts something like the cone which the plumber uses to open a pipe and thereby is detrimental. If it becomes adherent to the wall, as Dr. Marcy suggests, perhaps it thereby tends to strengthen the ring. If it is absorbed as we know in other cases similar processes are absorbed, for example in the callus of bone, then as Dr. Marcy has said there is obtained, in several weeks or months, the same result as he obtains at the time of the operation. The advantages of Dr. Marcy's suture I think are something very great. In these operations the changing of the sutures into connective tissue must be so much gain. The fact that sutures are put in in superimposed layers is also, I think, a great gain. I have aided Dr. Marcy in this operation in many cases, and I have, as testimony in its favor, the results where he has performed it upon myself.

DR. WHITMAN: Of course the sac becomes adherent, for the fresh surface resulting from its dissection is placed upon the fresh surface formed by the separation of the peritoneum about the internal aspect of the ring.

As to Dr. Marcy's treatment of the sac, it only differs from the ordinary operation in that he sews up the sac with a special stitch, and cuts it off, instead of simply tying it and cutting it off. It seems unlikely that any great advantage is thus obtained.

DR. MARCY's method of sewing up the canal must close it in a very thorough manner.

DR. GREEN: It seems to me that theoretically this operation of MacEwen promises more than any other operation that has yet been devised for the radical cure of hernia. Of course it is too soon for us to be sure that it is going to prove as beneficial as we hope. We have been disappointed so much in the previous operations for radical cure that I think it leads us to be a little sceptical in regard to this one. But I hope it will be tried here, and in the case of adults.

In children a large proportion, if they are carefully looked after, can be cured by the wearing of a truss. Perhaps not as surely as they would be in this way. I should think well of doing this operation in the case of children. In the case that Dr. Whitman shows to-night he has a firmer closure of the ring than one often sees from the radical cure. Two or three years is not sufficient. I often see them recur after a longer period than that.

DR. WHITMAN: Speaking of recurrence, there are some very interesting observations in the article edited by Professor Socur, in which it is stated that three-fourths of all recurrences take place in the first year. After the first year the patient has but one chance in fifty of having a recurrence.

DR. GREEN: There is no question but that the first year is the time when recurrence is very much more likely to take place. I have seen a good deal of it in the case of Heaton's operation. The recurrence there is a very common thing. Usually there is a large number of cases in the first year. I have known a good many ruptures to come down three or four years after the operation.

DR. WARREN: I think Dr. Green has touched the main point that most operations that have been hitherto devised have not been attended with so uniform success as MacEwen claims for his. And MacEwen's published cases are still, of course, small as compared with those of any other operation of an older date. MacEwen, therefore, has got to stand the test of time which the others have gone through.

A great deal was claimed for Wood's operation, yet we know that a great many failures followed it eventually. Although Wood still claims very satisfactory results, I do not think the profession has fully indorsed him. So with other operations for radical cure. What interests me in MacEwen's operation is not so much the theoretical statements as the fact that his operations are so uniformly successful. Perhaps that may be due to his skill as an operator, to his manipulation, dressing, etc.

The members of the profession are still undecided as to what operation to select. The operations of older date show a great many failures. Thus far, although perhaps the returns are not all in, MacEwen's operation seems to have a good show. When they are all in, whether they will be so favorable time only can show. It seems to me that eventually we shall get satisfactory results.

THE NEW YORK ACADEMY OF MEDICINE.

STATED Meeting, March 1, 1888.

DR. EDWARD B. BRONSON read a paper on

PREVENTIVE TREATMENT IN THE PRIMARY STAGE OF SYPHILIS.

By preventive treatment, he said, was not necessarily meant abortive treatment; but it embraced all measures tending in any degree to abridge or mitigate the subsequent course of infection and its effects on the constitution. The utility of any such measures would depend, first, on what the nature or essential quality of syphilitic infection is, and, second, on the special status of this infection during the primary stage of the disease. Of syphilitic infection, however, we had no positive knowledge, either as to what constitutes its essential element or what is its mode of progress; so that, until more light was shed upon the unsolved problem, we had to make the most of what there was.

The question in the form in which it immediately presented itself might be stated as follows: Are the indications thus far afforded by our imperfect knowledge of syphilitic infection such as to render any attempt at preventive treatment in the primary stage of

the disease unavailing and absolutely hopeless, as is maintained by many? There were two modes of approaching this question, one theoretical, and the other empirical.

In considering the indications furnished by the pathological conditions in syphilis, the first inquiry was naturally directed to the essential cause of the disease. Here, all was, as yet, hypothetical, and the most that we could do was to accept provisionally that view by which most was explained. No theory accounted for the observed phenomena of syphilitic infection so satisfactorily as that which attributes them to the presence and growth in the tissues of certain specific micro-organisms. Thus far, the microbe of syphilis had not been positively determined; but even were it fully established that syphilis is a parasitic disease, due to known forms of micro-organisms which could be cultivated outside of the body, it was by no means certain that the answer to the question of the utility of preventive treatment would be affirmative. Judging from experience in such diseases as tuberculosis and contagious anthrax, in which the specific germ had been identified, the success of antiseptic treatment was far from assured.

But the conditions in syphilitic infection were peculiar. Not only did the inoculation usually take place at a single point where it was freely accessible to manipulative procedures, but there were indications, in the slow and gradual progress of the disease, that general infection does not take place immediately, while there was a temporary sojourn of the virus in the region where first implanted. After describing the phenomena presented in the ordinary course of syphilitic infection, Dr. Bronson remarked that the most satisfactory explanation of the various events was that when first implanted in the tissues, the virus does not immediately pass into the general circulation, or what portion does is insignificant; that, mainly at least, it is at first confined to the spot where the future chancre is to develop; that here finding a favorable soil, it grows and slowly increases till its intrusive presence becomes a source of offense to the tissue harboring it, and gradually inflammatory reaction results. From this source of generation the virus contaminates, sooner or later, the nearest lymphatic glands, which in turn become other sources of supply, until, finally, from these multiple foci, the whole organism becomes infected. According to this view, the main route to the general circulation was by way of the lymphatics and through the *receptaculum chyli*. The pathological conditions seemed to imply that the disease advanced by way of the lymphatics in a manner analogous to the diffusion of the malignant tumors.

Whether, however, in syphilis the contamination advanced by such regular approaches from one gland to another that any definite interval could be said to exist between the affection of one gland and that of the next in succession was very doubtful.

In the indications presented up to this point, he went on to say, we found nothing incompatible with the position that during the primary period of syphilis the disease is located within the vicinity of the point of inoculation; but the view was current among syphilographers that the manifestations of this stage are always anticipated by infection of the general system. According to this position, directly upon its inoculation, the syphilitic virus passed into the general circulation, and the incubation pertained, not

to any *materies morbi* in the vicinity of the point of inoculation, but to something in the blood; while the initial lesion was the first tangible sign of the blood disease; reflected in some arbitrary and inexplicable manner to the spot where the virus affected its original entrance.

Two facts were alleged concerning the primary stage of syphilis upon which the theory of the symptomatic character of the initial lesion was based: (1) That an individual who has been inoculated with syphilis has always acquired immunity from any subsequent inoculation of the syphilitic virus before the chancre develops; and (2) that extirpation of the chancre does not prevent the regular course of the disease. That there was a period within a certain time after inoculation when the tissues were not refractory to a second implantation of the virus, was shown by the fact that when a second or third inoculation takes place within a short period from the first exposure, successive and multiple chancres result. The immunity, therefore, was not established at once. But it was claimed that after the chancre had once formed, constitutional infection was an accomplished fact, and immunity was then complete. In verifying this point, however, the length of time it required for the chancre to develop should be taken into consideration. The second inoculation might have its effects forestalled and prevented by constitutional infection intervening before the completion of its inoculation. While it was true that as a general rule auto- and re-inoculation in the primary stage failed to produce any perceptible effect, a sufficient number of cases had been reported to show that the rule was not invariable, and that if immunity were the test of general saturation with the syphilitic poison, we had to conclude that the chancre is not positive evidence of constitutional disease, and hence cannot be its symptom.

It might be conceded, however, that in the majority of cases immunity did precede what is known as secondary syphilis. It seemed not improbable that a slight degree of general infection might exist in primary syphilis, which, though sufficient to confer immunity upon the individual from any second installment of the virus, was yet insufficient to cause general disease. A notable illustration of such an immunity was shown in the case of the mother of a syphilitic child, who, notwithstanding she might at no time present any outward sign of syphilitic infection, was immune from contagion, and suckled her child with impunity. Moreover, there was nothing in the view proposed, that did not accord with the results of preventive inoculation in other infectious diseases.

The results of ectrotic treatment had thus far afforded but little encouragement. It was affirmed to be the rule in infectious disease generally, which take their origin from a local point of inoculation, that it is impossible to prevent general infection. In syphilis, however, all the obvious signs pointed to a much slower development than in the others. Certain results reported by Sigmund would seem to be clearly in favor of abortive canterization immediately after syphilitic inoculation. Of 57 patients who presented themselves with abrasions after suspicious connection, 35 were canterized; and of these, only 10 developed syphilis. Out of the 22 not interfered with, 11 became syphilitic. There were also indications that the earlier the canterization was practised, the better the chance of its success. Thus, of the 35 cases canter-

ized, in 24 this was done from the first to the third day following the suspicious exposure; and of these only three became syphilitic. Of 11 canterized from the fifth to the tenth day, 7 became syphilitic; and this would tend to show that after the fourth day the chances were against the success of the operation.

Most discouraging was the well-known case reported by Berkely Hill, in which a patient with a torn frenum was canterized twelve hours after a sexual encounter, returned a month later with the cicatrix indurated, and afterward developed constitutional syphilis. A possible loop-hole of escape might be found in the supposition that the patient had exposed himself to the disease during his month of absence. Still, there was evidence enough to show that the virus of syphilis passes beyond the reach of caustics within a short time after its inoculation. *A fortiori* by the time the chancre was developed it should be still further removed. But, though inaccessible to caustics, it had been hoped that the infected part might be included in a free incision, and while the results reported had shown a most exasperating diversity, the fact remained that in a considerable percentage of the cases the occurrence of constitutional syphilis was apparently prevented.

It could not be said, however, that the results of excision made conclusively either for or against the hypothesis of the local character of primary syphilis. As a manifestation of the primary stage, the chancre was hardly of more importance than the indolent adenopathy. That the indurated lymphatic glands in the vicinity of the initial lesion were contributory sources of infection there was little reason to doubt; and were the initial lesion removed, they would doubtless still suffice to contaminate the system.

While, then, it could not be affirmed of any period in the course of the malady that the disease is strictly limited to the site of the initial lesion, the proposition that syphilis is at first essentially a local disease remained still uncontroverted. As to the hope of interference afforded by the views now presented, Dr. Bronson said it had been intimated the answer to the question might be equally valid whether based upon theoretical or empirical grounds. Empirically, the answer was so ambiguous that we had been forced to have recourse to theory; and here we found the omens not unpropitious. An infection whose limits were circumscribed and more or less definable was a very different thing to one that had already taken possession of the entire organism. During the forty days' sojourn of the enemy in its outlying camps, while the insidious infection was slowly advancing its outposts from the periphery to the vital centres, he asked, are there no other resources than in excision of the initial lesion, which is but one of the multiple foci of infection, or this, together with extirpation of a few inguinal glands, and in constitutional treatment?

Excision of the initial lesion might have accomplished something. Certainly, where practicable, it was a perfectly rational, safe, and proper procedure. It was removing an annoying symptom and a possible source of danger to others. In a few instances excision of inguinal glands, together with the initial lesion, had been reported, but thus far without noteworthy results, though it was by all means desirable that experiments in this direction should be continued. Inspired by the success of Pasteur in his preventive inoculations for charbon, it occurred to Diday that by

inoculating a patient recently infected with syphilis with an attenuated syphilitic virus, the course of the disease might be prevented; but this idea had never been put in practice. As to the value of medicinal anti-syphilitic treatment during the primary stage, there was a diversity of opinion. While it was pretty generally conceded that the employment of mercury in this stage tends to retard the appearance of constitutional symptoms, the apprehension had been expressed by some that in repressing the outward manifestations of infection, we were risking a more serious implication of internal organs. There was an inconsistency, however, in the idea that for the mouth or so of primary syphilis the same remedy was to be shunned because of dangerous after-effects, whose continued employment during the years of the constitutional disease was accepted without demur. In many instances, mercury was given internally in syphilis for strictly localized lesions, where the general system showed no sign of the disease, and with unquestionable effect; while there was hardly any one but admitted that when the chancre was formidable in size, or slow in yielding to local measures, a mercurial course would hasten its resolution.

Supposing that mercury does not act as an antiseptic in syphilis, it was very questionable whether it could have any effect upon germs circulating in the blood; and it was much more probable that the effect would be exerted where both the germs and the mercurial would be apt to accumulate, as at such places of elimination as the skin, or where deposited in the tissues. That mercury does exert a most decided influence upon the local manifestations of syphilis when topically applied, we had undoubted evidence; then why should not this potent influence be brought to bear directly upon those local lesions which were also dangerous foci of infection in the primary period of the disease? It was only recently that the so-called "regional treatment" of primary syphilis had received much attention, and as yet no remarkable results had been reported. Dr. Bronson said that his own experience had been mainly confined to certain experimental attempts as to the possibility of the method, and it was almost purely on theoretical grounds that he recommended this treatment.

The scheme consisted in the local use of anti-syphilis by a method designed to bring the remedy in direct communication with the whole of the affected region in primary syphilis, including more particularly the initial lesion and the diseased glands. As commonly employed, the regional treatment had consisted chiefly in the use of mercurial hypodermics beneath the initial lesion (unless this was excised) and into the mass of the indurated lymphatic glands. But the plan might be easily extended. The field of operation might include all of that district whose lymphatic vessels tend in their course towards the ganglia which are the seat of the disease. Where the initial lesion was situated upon the genitals, the area most available would consist of the external genitals, the perineum, and the upper inner and anterior aspect of the thighs, together with the inguinal region and lower part of the abdomen. By multiple small injections and by innunciations within this area, the remedy might be introduced little by little into the lymphatics, with the hope of its being conveyed in sufficient amount to the diseased glands to destroy the infectious germs, or to retard their multiplication.

The only agent thus far employed for this purpose was mercury. No substitute for it had been found, and the question was how to introduce this irritating substance into the affected region with the least amount of offence to the normal tissues, but in sufficient quantity to exert its antidotal or antiseptic influence upon the germs of the disease. When hypodermics were used it was not necessary that the drug should be injected in large quantity in any one spot, nor in a concentrated form. A twentieth of a grain, or less, of the bichloride, introduced in separate injections of not over the hundredth of a grain each, would afford a more reasonable hope of effectively reaching the seat of the disease than a much larger dose given by the mouth. Dr. Bronson said he had used a solution of one part in four hundred or five hundred of mucilage and water, with a small quantity of common salt added. Of this four or five injections were made, of four or five minims each, distributed over different parts of the cutaneous area described. The discomfort caused by the injections was insignificant, especially if care were taken to avoid any escape of the fluid into the corium. The number and frequency of the injections must depend on circumstances and on individual judgment. Into the skin of the abdomen and thighs they might be repeated daily, or every second or third day. Together with these injections, but more especially in situations where the latter were less admissible, as in the perineum and over the penis and scrotum, innunciations also might be employed; and for this purpose a mercurial soap was preferable to mercurial ointment. Many modifications of the plan thus outlined would doubtless suggest themselves. It might be said that regional treatment was also constitutional treatment, as in a degree it no doubt was; but it was something more, and surely it was something better than doing nothing at all.

DISCUSSION.

DR. EDWARD L. KEYES regretted that Dr. Bronson had not been able to present more practical results from the method advocated in the paper. His impression had always been that the disease becomes general from the time it is acquired, (before the appearance of the primary lesion, which occurred only after a period of inoculation); and he believed, therefore, the virus at once got beyond the lymphatic chain. He related a case in which, notwithstanding the complete excision, within twelve or fifteen hours after a suspicious connection, of a small livid papule on the back of the penis, the most marked constitutional symptoms subsequently occurred. In this instance there was no further trouble whatever about the local lesion, and not the slightest enlargement of the inguinal glands. Whether washing the parts immediately after suspicious contact would in any case have the effect of preventing infection of the system he could not say.

The objection to local treatment, before the diagnosis of syphilis was established, with the only agent that was of any service afterwards consisted in the fact that such a course was always likely to throw more or less discord into the life of the patient, while if constitutional symptoms did develop they are apt to run an irregular course. He then related the case of a medical student who, contrary to his advice, commenced a mercurial course in consequence of a slight abrasion of the prepuce. At the end of six months, no

evidence of syphilis having in the meantime presented itself (if the enlargement of a single one of the post-cervical glands were excepted), he gave up the treatment. Within two years, however, he became the subject of hemiplegia, and eventually died of syphilitic brain disease. As a rule, he believed it was much better to delay treatment until the diagnosis was confirmed by the appearance of secondary symptoms. Otherwise a patient might be treated for syphilis who did not have the disease at all; and he referred to an instance that he had known in which a gentleman who never had the disease took bichloride of mercury for twelve years in consequence of a mistake of this kind.

DR. ROBERT W. TAYLOR said that he agreed with Dr. Bronson that the history of the disease and the analogic evidence afforded by certain other infectious diseases showed that syphilis is at first a local affection; but a very extended experience had convinced him that neither excision nor cauterization would prevent constitutional infection. There was already evidence enough to show that syphilis could not be exterminated at the radicals. Bloodvessels were frequently found running up to the chancre, and the new-growth cells germinated indefinitely; so that he did not believe that a single case of true syphilis had ever been aborted. He thought Dr. Bronson was wrong in regard to the immunity of the mother of a syphilitic child, for, while it was true that a woman could have a syphilitic child and yet not take the disease herself, it was a fact, as shown by Caspari, that she might contract the disease in the ordinary way.

In primary syphilis, Dr. Taylor went on to say, the circumstances were entirely different from what they were later on. We had to deal with a nascent disease which exhibited marked activity, and hence the most prompt remedies were required to destroy the new growths that were forming. He believed it was impossible, however, to safely employ mercury, the only agent at our command for this purpose, in sufficient quantity to have the desired effect. He agreed with Dr. Keyes that it was most rational to begin the treatment with the secondary stage of the disease. By so doing a more orderly sequence was secured, and the moral effect upon the patient was also much greater. As far as we could judge, mercury acted by causing fatty degeneration of the syphilitic cells, and as these cells did not become matured until the constitutional symptoms of the disease appeared, he thought it was altogether irrational, as a rule, to use this agent until the secondary stage was reached, especially since it had been shown that syphilis does not run the tractable course in those who are treated early as in those from whom mercury is withheld until after the primary stage. There were, however, certain conditions which called for early treatment, and among these were the following: When the chancre is so large as to impede urination, when there is phagadæna; and when the chancre is situated about the eyes, mouth or fingers, where it is liable to communicate infection to others. There were also social reasons sometimes why early treatment should be instituted.

DR. BRONSON said that in the paper he had acknowledged that his views were based largely on theoretical grounds. He held that it was necessary that the subject should be approached in a speculative spirit, and what he had endeavored to do was to point out the indications which called for early treatment.

If the disease was primarily constitutional there were no such indications; while the fact that the disease was primarily local did not imply that excision of the initial lesion should abort it. In his argument he had expressly discarded excision as a means of abortion, because by the time the chancre appeared the disease had advanced to the lymphatics. In order to abort it it would be necessary that all the foci of infection should be eliminated, and this had been proved to be impossible. Believing, however, that the disease was still local, he thought it was philosophical to treat it regionally, and thus counteract the infection as far as possible in this early stage. The objections which have been urged to such a course seemed to him altogether trivial, and he felt confident that any patient would prefer to take the chances of this prompt treatment rather than do nothing until the fully developed secondary symptoms presented themselves. Although he had no results to offer, he could abundantly testify from his own experience that the method was entirely feasible, and he certainly thought it was worth a fair and systematic trial.

MEETING OF THE MASSACHUSETTS MEDICO-LEGAL SOCIETY.

W. H. TAYLOR, RECORDING SECRETARY.

FEBRUARY 1, 1888. The meeting was called to order by PRESIDENT WINSOR. Twenty-three members were present. Records of the last meeting were read and approved.

DR. R. H. FITZ, chairman of the committee on preparation of a blank form for autopsy returns made his report. He acknowledged the receipt of criticisms from various medical examiners, and proceeded to discuss them. They were mainly as follows:

- (1) The blank form is too full and complete.
- (2) It is not detailed enough.
- (3) Its phraseology might be improved.
- (4) It does not give enough blank space.
- (5) It will aid the defendant.

DR. FITZ stated that the committee had carefully considered the objections and answered them at some length. He said that he thought the objections could be met without changing the form, and recommended its adoption with a few unimportant changes. The word *inquest* should be left off the outer fold of the blank, and a declaration that autopsy is necessary inserted just below the statement of name, age, etc. He moved the following for adoption by the Society:

I. That the Society provides its members with copies of the printed form prepared by the committee, and a sufficient number of blank pages of corresponding make for use in recording the evidence furnished by a post-mortem examination.

II. It further recommends the general use of such blanks in reporting to the judicial officers the results of a medico-legal investigation requiring a post-mortem examination.

III. A blank should accompany the above and should interpret the evidence contained in the record of autopsy, as well as include a statement of such additional facts as were necessary to determine the cause and manner of death, and the committee recommends that the standing committee be requested to prepare a blank for this purpose.

MEDICAL EXAMINER HARTWELL moved that the

report be received and its recommendations adopted—seconded by Medical Examiner Mead.

MEDICAL EXAMINER PINKHAM suggested that a statement of the supposed time of death might be inserted with advantage. Would also have headings for rigor mortis and post-mortem discoloration. In the section on injuries, would have headings for varieties of wounds, fractures, etc. Would crowd printed headings farther toward left side of the form, and draw a heavy line to limit the blank space.

MEDICAL EXAMINER ADAMS made some remarks regarding the phraseology of the blank form, and inquired of Dr. Fitz the use of the form.

Dr. FITZ replied that such forms are used abroad as an aid to the medical examiner, the court, and expert witnesses. He thought that it might be as useful here as there.

MEDICAL EXAMINER PRESBREY believed in the use of a very complete system for aid to the medical examiner, but would object to such returns to the District Attorney.

Further discussion was made by members Adams, Morse, Presbrey, Pinkham and Fitz. Medical Examiner Pinkham moved to lay the report on the table, and take it up at the June meeting—lost.

MEDICAL EXAMINER PINKHAM moved adoption of his suggestions as an amendment to the blank—lost.

Dr. FITZ moved that the report be accepted and its recommendations be voted on seriatim. The motion prevailed; and the Society adopted recommendations I and III, and rejected II.

A communication from the Secretary of the Georgia Medical Society requesting cooperation in securing legislation favoring importation of surgical instruments, drugs, and medical supplies, free of duty, was laid on the table.

MEDICAL EXAMINER TOWER moved that the Corresponding Secretary be instructed to print three hundred copies of the blank form for autopsy returns, and send three copies to each medical examiner belonging to the Society. The motion was adopted.

On recommendation of the Executive Committee, Medical Examiner O. H. Howe, of Cohasset, was unanimously elected a regular member of the Society.

MEDICAL EXAMINER PINKHAM reported an interesting case of manslaughter from a blow on the temple which fractured a remarkably thin skull.

Voted to adjourn.

MASSACHUSETTS MEDICAL SOCIETY.
SUFFOLK DISTRICT.
SECTION FOR CLINICAL MEDICINE, PATHOLOGY AND HYGIENE.

ALBERT N. BLODGETT, M.D., SECRETARY.

JANUARY 25, 1888.

By the courtesy of PROF. F. W. PUTNAM, the Section was convened in the hall of the Peabody Museum at Harvard University, Cambridge. The night was one of the most inclement of the entire winter, which greatly diminished the number of those who would have attended the meeting. The Chairman, Dr. A. L. MASON, being absent, Dr. G. H. LYMAN was unanimously chosen Chairman *pro tem*.

PROFESSOR PUTNAM addressed the Section upon

the subject of the recent excavations which have been carried out under his direction in the Ohio Valley, in a location where abundant evidences of a prehistoric residence of man exists, and in which researches much valuable information concerning the habits and customs, as well as of the diseases and their treatment in the unknown races of men which occupied this portion of our country at that remote period, have been gained.

The time during which the peoples lived whose remains and whose handiwork we now find cannot be accurately determined by years. It is determined by the geological chronology to have been at or subsequent to that period during which the glacier which covered a great part of this continent was retreating toward the north, from the gradual elevation of the temperature of this part of the earth's surface. At this time and from this cause, a great moraine was left, extending from the vicinity of New York across Ohio, to Cincinnati, then turning northward to the Rocky Mountains, near St. Paul. All this region, and all to the north of it, was covered with ice, and at the lower edge of the ice-field, where the melting line of the ice was reached, there was left a line of gravel extending across the continent. Man was at that time living on the south side of this moraine. The melting of the ice and the consequent rise of the waters during the period spoken of brought down great amounts of debris, gravel, etc., from points higher up, and gradually covered the surface of the ground with a layer of soil varying in thickness from six to thirty feet. In many parts of the continent which were situated at the border of this moraine, and which were similarly affected by the melting of the ice and the retreat of the line of the glacier, there are found the same relics of human life, the same implements, the same ornaments, and these are always found in precisely the same geological formations, underlying the same geological strata. Thus quartz tools of similar pattern and quality have been discovered at Trenton and at Little Falls, Minn. We find, then, that this portion of the globe was inhabited by man at a time when a large portion of the American continent was covered with ice and uninhabitable. On the southern side of the ice was the residence of man. As the ice retreated, man moved further and further toward the north, being crowded by other races from the south, until this form of civilization was extinguished throughout this region. The only existing remnant of the peoples who inhabited the territory at the edge of the great moraine is found in the Esquimaux, who still preserve the type of skull, and the shape of the cranium and face peculiar to the race occupying the area of the ice-moraine, whose skeletons are still preserved in the mounds which are now being explored. The skull of these early inhabitants of this part of the country is long and narrow, and is keel-shaped, the parietals are high, and the head is narrow. The Indian, so called, has a skull long and narrow, but not keeled. This form of skull is found along the coast of California, extending along the base of the Rocky Mountains, through the Mississippi Valley and that of the Columbia River, the upper Missouri, thence along the Great Lakes, and down the valley of the St. Lawrence, with many branches to the north and south. This race evidently reached America by the Aleutian Islands from Asia, and the first traces of their presence on this continent are to be found near

the Rocky Mountains. From the West the race pushed to the Atlantic, near the Carolinas, and then turned backward and to the north to the valley of the Ohio. The broad, short head which is also found in this region belongs to a tribe which came from the South, being found in Mexico and in northern parts of South America. They evidently originated in the southern islands of the Pacific, and are of distinctly Mongolian type. These peoples advanced toward the North, and came into contact with the longheads in the valley of the Ohio. In this region their burial places are still found, and their remains are discovered in great number.

Professor Putnam gave a detailed and most interesting account of the habits of these people, their religious observances, their mode of dress, their taste in ornamentation, the textures of their clothing, and materials of war and domestic use. He then exhibited a series of pathological specimens collected from the mounds and other burial places, or found in accidental locations, showing unmistakable evidences of surgical knowledge and operative skill among these primitive people. Several cases of fracture of the long bones were shown, in which the bone had united at an angle, with great shortening. A tibia was exhibited in which there was the unmistakable evidence of a perforation of the tuberosity into the interior of the head of the bone, produced by a surgical instrument of the nature of the trephine. Several cases of injury to the skull were observed, in which there had been surgical treatment of the patient, with subsequent processes of repair, and the recovery of the patient.¹

Before adjournment, DR. LYMAN said that the members of the Suffolk District Medical Society would consider him derelict in his duty, were he not to offer to Professor Putnam their thanks for his great kindness in opening the museum to its Section of Clinical Medicine, and for the delightful and interesting lecture upon his recent exploration in the Miami Valley, with which he had favored them. He begged to assure him that the Section would cordially appreciate his courtesy.

Recent Literature.

Doctor and Patient. By S. WEIR MITCHELL, M.D., LL.D. Philadelphia: J. B. Lippincott Co. 1888.

This little volume of 177 pp. octavo, consists of an introduction and six essays on as many different subjects, which have more or less connection with each other, and easily range themselves under the title chosen by the author. In the introduction Dr. Mitchell says: "I was tempted when I wrote these essays to call them lay sermons, so serious did some of their subjects seem to me. They touch, indeed, on matters involving certain of the most difficult problems in human life, and involve so much to war or make human character, that no man could too gravely approach such a task. Not all, however, of these chapters are of this nature, and I have, therefore, contented myself with a title which does not so clearly suggest the preacher." Even though the title may not suggest the preacher, the pages everywhere sug-

gest the experience of the confessor. And the physician, certainly he who has to deal with the class of patients with the treatment of which Dr. Mitchell's name is especially associated, is, in Protestant countries, the father-confessor of this generation. Though modestly stating that the book is for popular use, rather than for the profession, the latter will find in it quite as much that is wise and helpful.

We cannot forbear quoting with the heartiest approval a few more paragraphs from the introductory portion: "What I shall have to say in these pages will trench but little on the mooted ground of the differences between men and women. I take women as they are to my experience. For me the grave significance of sexual difference controls the whole question, and, if I say little of it in words, I cannot exclude it from my thought of them and their difficulties. The woman's desire to be on a level of competition with man and to assume his duties is, I am sure, making mischief, for it is my belief that no length of generations of change in her education and modes of activity will ever really alter her character. She is physiologically other than man."
